EDITORIAL: Personal reflections 1
G. Smith

CLINICAL INVESTIGATIONS

Ropivacaine 0.75% for extradural anaesthesia in elective Caessarean section: an open clinical and pharmaco-kinetic study in mother and neonate.... 3
C. P. J. Morton, S. Bloomfield, A. Magnusson, H. Jozwiak and J. H. McClure

Serum concentrations of bupivacaine during prolonged continuous paravertebral infusion in young infants 9
S. L. W. Cheung, P. D. Booker, R. Franks and M. Pozzi

Gut mucosal perfusion in infants undergoing cardiopulmonary bypass: effect of preoperative captopril 14
P. D. Booker, A. J. M. Davis and R. Franks

Interactions between mivacurium and pancuronium 19
K. S. Kim, J. C. Shim and D. W. Kim

Blood flow and mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles.. 24
M. Abdulatif and M. El-Sanabary

Comparison of extradural and general anaesthesia on the fibrinolytic response to total knee arthroplasty 29
N. E. Sharrock, G. Go, P. Williams-Russo, S. B. Haas and P. C. Harpel

Cardioventilatory coupling during anaesthesia......... 35
D. C. Galletly and P. D. Larsen

Effect of domperidone on the ventilatory response to transient hyperoxia in patients anaesthetized with isoflurane........ 41
I. T. Foo, P. M. Wsarren and G. B. Drummond

Accuracy and clinical performance of a continuous intra-arterial blood-gas monitoring system during thoracoscopic surgery..... 47
A. Zollinger, D. R. Spahn, T. Singer, M. P. Zalunardo, S. Stoehr, W. Weder and T. Pasch

Midlatency auditory evoked potentials and motor signs of wakefulness during anaesthesia with midazolam 53
D. Schwender, M. Daunderer, N. Schnatmann, S. Klasing, Ul. Finsterer and K. Peter

Intradermal compared with prick testing in the diagnosis of anaesthetic allergy........ 59
M. McD Fisher and C. J. Bowey

Plasma dilution and the rate of infusion of Ringer's solution 64
R. G. Hahn and C. Svensén

LABORATORY INVESTIGATIONS

R22290

Beneficial effect of concomitant administration of isoflurane and nicorandil........ 68
V. Piriou, S. Ross, D. Pigott, R. Evans and P. Foex

Effect of halothane on K^+ and carbachol stimulated [^{3}H]noradrenaline release and increased [Ca^{2+}]$_i$ in SH-SY5Y human neuroblastoma cells........ 78
R. Archeson, K. Bjornstrom, R. A. Hirst, D. J. Rowbotham and D. G. Lambert

Role of endothelium in the modulation of isoflurane-induced vasodilatation in rat thoracic aorta.......... 84
P. Kirstetter, F. Lagneau, O. Lucas, V. Krupa and J. Marty

Halothane reduces reperfusion injury after regional ischaemia in the rabbit heart *in vivo*........ 88
W. Schlack, B. Preckel, H. Barthel, D. Obal and V. Thämer

Effects of alfentanil on cerebral haemodynamics in an experimental model of traumatic brain injury...... 97
M. J. Souter, P. J. D. Andrews, I. R. Piper and J. D. Miller

Quantitative study of Lowe's square-root-of-time method of closed-system anaesthesia........ 103
J. M. Couto da Silva, W. W. Mapleson and M. D. Vickers

REVIEW ARTICLE

Thoracoscopic sympathectomy in the treatment of palmar hyperhidrosis: anaesthetic implications.... 113
B. Fredman, D. Olsfanger and R. Jedeikin

SHORT COMMUNICATIONS

Extradural buprenorphine suppresses breast feeding after Caesarean section........ 120
M. Hirose, T. Hosokawa and Y. Tanaka

Administration of magnesium sulphate before rocuronium: effects on speed of onset and duration of neuromuscular block........ 122
B. Kussman, G. Shorten, J. Uppington and M. E. Comunale

Dystrophin deficient *mdx* muscle is not prone to MH susceptibility: an *in vitro* study........ 125
N. Mader, H. Gilly and R. E. Bittner

Effects of ketamine and pentobarbitone on acetylcholine release from the rat frontal cortex *in vivo* 128
T. Kikuchi, Y. Wang, H. Shinbori, K. Sato and F. Okumura

ABSTRACTS

Proceedings of the Anaesthetic Research Society, Leicester Meeting, March 20–21, 1997........ 131P

CORRESPONDENCE

Absence of memory for intraoperative information.. 143
Sevoflurane or halothane for paediatric endoscopy .. 143
Spinal anaesthesia: effect of the site of injection on the spread of analgesia........ 144
Cuff deflation for easier weaning from ventilation... 145
Prophylaxis against deep vein thrombosis 145
Intraocular pressure and suxamethonium 146

BOOK REVIEWS

Handbook of Critical Care, 2nd Edn........ 147
Practical Obstetric Anaesthesia........ 147
Cambridge Textbook of Accident and Emergency Medicine........ 147

AUGUST

EDITORIAL: Resuscitation........ 149
P. J. F. Baskett and L. Strunin

RESUSCITATION

Basic life support........ 151
A. J. Handley

Management of the airway and ventilation during resuscitation ... 159
D. A. Gabbott and P. J. F. Baskett

Advanced life support guidelines ... 172
C. E. Robertson

Paediatric and neonatal life support ... 178
D. A. Zideman

Drugs in modern resuscitation ... 188
R. Vincent

Peri-arrest arrhythmias ... 198
D. Chamberlain

Fibrillation and defibrillation of the heart ... 203
L. L. Bossaert

Immersion, near-drowning and drowning ... 214
F. St C. Golden, M. J. Tipton and R. C. Scott

Aspects of resuscitation in trauma ... 226
J. P. Nolan and M. J. A. Parr

Uniform reporting in resuscitation ... 241
W. F. Dick

Ethical aspects of resuscitation ... 253
M. Mohr and D. Kettler

CORRESPONDENCE

Oxygenation criteria – a plea for more information ... 260
Lateral positioning for regional analgesia during labour ... 260
Interactions between mivacurium and prilocaine ... 262
Effects of volume on spinal anaesthesia with 0.25% hyperbaric bupivacaine ... 262
Converting pH and H^+ ... 262
"Renal" dopamine ... 263

BOOK REVIEWS

Manual of Drug Interactions for Anaesthesiology, 3rd Edn ... 265
Critical Care, 3rd Edn ... 265
Pain Management for the Practising Physician ... 265
The Pulmonary Circulation: Moving From Passive to Active Control ... 266
The Pulmonary Artery Catheter in Critical Care – A Concise Handbook ... 266
Hyperthermic and Hypermetabolic Disorders ... 266
Intensive Care Manual, 4th Edn ... 266
Critical Care Medicine: Perioperative Management ... 267
Stabilisation and Transport of the Critically Ill ... 267

Errata ... 268

SEPTEMBER

EDITORIALS:

I So just who was James "Young" Simpson? ... 271
S. M. Rae and J. A. W. Wildsmith

II Propofol in paediatric intensive care ... 274
D. J. Hatch

CLINICAL INVESTIGATIONS

Metabolic, biochemical and haemodynamic effects of infusion of propofol for long-term sedation of children undergoing intensive care ... 276
P. H. Martin, B. V. S. Murthy and A. J. Petros

Comparison of sevoflurane and halothane for outpatient dental anaesthesia in children ... 280
S. T. Paris, M. Cafferkey, M. Tarling, P. Hancock, P. M. Yate and P. J Flynn

Comparison between halothane and sevoflurane for adult vital capacity induction ... 285
J. E. Hall, T. A. Oldham, J. I. M. Stewart and M. Harmer

Laryngeal mask airway and uncuffed tracheal tubes are equally effective for low flow or closed system anaesthesia in children ... 289
D. Frohlich, B. Schwall, W. Funk and J. Hobbhahn

Caudal tramadol for postoperative analgesia in paediatric hypospadias surgery ... 293
D. P. Prosser, A. Davis, P. D. Booker and A. Murray

Comparison of single, end-holed and multi-orifice extradural catheters when used for continuous infusion of local anaesthetic during labour ... 297
M. A. S. Dickson, C. Moores and J. H. McClure

Transient neurological symptoms afer spinal anaesthesia with 4% mepivacaine and 0.5% bupivacaine ... 301
A. Hiller and P. H. Rosenberg

Comparison of volume controlled with pressure controlled ventilation during one-lung anaesthesia ... 306
M. Tuğrul, E. Çamcı, H. Karadeniz, M. Şenturk, K. Pembeci and K. Akpir

Acute effect of mitral valve replacement on extravascular lung water in patients receiving colloid or crystalloid priming of cardiopulmonary bypass ... 311
W. Buhre, A. Hoeft, B. Schorn, A. Weyland, M. Scholz and H. Sonntag

Acute normovolaemic haemodilution decreases postoperative allogeneic blood transfusion after total knee replacement ... 317
D. Olsfanger, B. Fredman, B. Goldstein, A. Shapiro and R. Jedeikin

Ondansetron compared with metoclopramide in the treatment of established postoperative nausea and vomiting ... 322
P. Diemunsch, C. Conseiller, N. Clyti, J. P. Mamet and the French Ondansetron Study Group

Histological support for the difference between malignant hyperthermia susceptible (MHS), equivocal (MHE) and negative (MHN) muscle biopsies ... 327
P. Mezin, J.-F. Payen, J.-L. Bosson, E. Brambilla and P. Stieglitz

Detection of a novel mutation at amino acid position 614 in the ryanodine receptor in malignant hyperthermia ... 332
K. A. Quane, H. Ording, K. E. Keating, B. M. Manning, R. Heine, D. Bendixen, K. Berg, R. Krivosic-Horber, F. Lehmann-Horn, T. Fagerlund and T. V. McCarthy

Changes in inflammatory mediators during orthotopic liver transplantation ... 338
M. C. Bellamy, H. F. Galley and N. R. Webster

Environmental monitoring during gaseous induction with sevoflurane ... 342
J. E. Hall, K. A. Henderson, T. A. Oldham, S. Pugh and M. Harmer

LABORATORY INVESTIGATIONS

Effect of haemoglobin concentration on brain oxygenation in focal stroke: a mathematical modelling study ... 346
F. Dexter and B. J. Hindman

Actions of tramadol, its enantiomers and principal metabolite, O-desmethyltramadol, on serotonin (5-HT) efflux and uptake in the rat dorsal raphe nucleus ... 352
T. A. Bamigbade, C. Davidson, R. M. Langford and J. A. Stamford

Dopamine and intestinal mucosal tissue oxygenation in a porcine model of haemorrhage ... 357
R. Germann, M. Haisjackl, B. Schwarz, N. Salak, E. Deusch, W. Pajk, H. J. Wolf, B. Riedmann and W. Hasibeder

Effects of magnesium sulphate on the cardiovascular

system, coronary circulation and mycocardial metabolism in anaesthetized dogs 363
Y. Nakaigawa, S. Akazawa, R. Shimizu, R. Ishii, S. Ikeno, S. Inoue and R. Yamato

REVIEW ARTICLE

Pain after laparoscopy 369
J. I. Alexander

SHORT COMMUNICATIONS

Twitch augmentation and train-of-four fade during onset of neuromuscular block after subclinical doses of suxamethonium 379
S Y. Kim, J. S. Lee, S. C. Kim and W. Park

Spontaneous movements associated with rocuronium: is pain on injection the cause? 382
A. Borgeat and D. Kwiatkowski

Rapid tracheal intubation with propofol, alfentanil and a standard dose of vecuronium 384
R. Groener and D. G. Moyes

Haemolysis after etomidate: comparison of propylene glycol and lipid formulations 386
A. Doenicke, M. F. Roizen, R. Hoernecke, M Mayer, P. Ostwald and J. Foss

Enhanced choline acetyltransferase activity does not explain the action of inhaled convulsants 389
R. Griffiths, P. Ionescu, Z. Fang, D. D. Koblin and E. I. Eger

CASE REPORTS

Sevoflurane for difficult tracheal intubation..... 392
S. M. Mostafa and A. M. J. Atherton

Transient radicular irritation after spinal anaesthesia with 2% isobaric lignocaine. 394
D. Ramasamy and R. Eadie

Unsuspected difficult intubation caused by a laryngeal web 396
Z.-K. Chong, B. Jawan, Y.-Y. Poon and J.-H. Lee

EQUIPMENT

Laboratory evaluation of the 1-NOvent nitric oxide delivery device... 398
J. D. Young, M. Roberts and L. B. Gale

COMMENTARY

Clinical evidence for delayed chloroform poisoning 402

CORRESPONDENCE

Converting pH and H$^+$: a rule for the other thumb 410
MAC values of mixtures.................. 410
The expanding role of simulators in risk management 411

BOOK REVIEWS

Clinical Anaesthesia 412
Textbook of Neuroanesthesia with Neurosurgical and Neuroscience Perspectives........ 412

Erratum 413

OCTOBER

EDITORIALS:

I Postoperative respiratory dysfunction: is the site of surgery crucial?..................................... 415
H. McKeague and A. J. Cunningham

II ORG 21465, a new water-soluble steroid hypnotic: more of the same or something different? 417
J. W. Sear

III Meta-analysis: greater than the sum of its parts? 417
M. J. Souter and D. F. Signorini

CLINICAL INVESTIGATIONS

Postoperative spirometry after laparoscopy for lower abdominal or upper abdominal surgical procedures 422
J. Joris, A. Kaba and M. Lamy

Administration to humans of ORG 21465, a water soluble steroid i.v. anaesthetic agent.................... 427
J. R. Sneyd, P. M. C. Wright, M. Cross, P. Thompson, G. Voortman, M. M. Weideman, C. J. H. Andrews and C. J. Daniell

Computer-controlled infusion of ORG 21465, a water soluble steroid i.v. anaesthetic agent, into human volunteers 433
J. R. Sneyd, P. M. C. Wright, D. Harris, P. A. Taylor, P. C. M. Vijn, M. Cross, H. Dale, G. Voortman and P. Boen

Prognosis of intraoperative brachial plexus injury: a review of 22 cases 440
B. Ben-David and S. Stahl

Does the addition of clonidine affect duration of analgesia of bupivacaine wound infiltration in inguinal hernia surgery?.......... 446
S. Elliott, S. Eckersall, L. Fligelstone and S. Jothilingam

Comparison of suxamethonium and different combinations of rocuronium and mivacurium for rapid tracheal intubation in children........................... 450
M. Naguib, A. H. Samarkandi, A. Ammar and A. Turkistani

Effect of temperature and cardiopulmonary bypass on the pharmacokinetics of remifentanil 456
D. Russell, D. Royston, P. H. Rees, S. K. Gupta and G. N. C. Kenny

Influence of pulse oximeter lower alarm limit on the incidence of hypoxaemia in the recovery room.... 460
A. T. Rheineck-Leyssius and C. J. Kalkman

Does nitrous oxide antagonize sevoflurane-induced hypnosis?.................................. 465
T. Katoh, K. Ikeda and H. Bito

Effect of incremental doses of sevoflurane on cerebral pressure autoregulation in humans 469
S. Gupta, K. Heath and B. F. Matta

Comparison of isoflurane with propofol on respiratory cilia ....:.... 473
J. H. Raphael and M. W. Butt

Platelet function is inhibited by nitric oxide liberation during nitroglycerin-induced hypotension anaesthesia.. 476
H. Aioki, M. Inou, T. Mizobe, M. Harada, H. Imai and A. Kobayashi

Validity of acoustic quantification colour kinesis for detection of left ventricular regional wall motion abnormalities: a transoesophageal echocardiographic study 482
T. Hartmann, N. Kolev, A. Blacher, C. Spiss and M. Zimpfer

LABORATORY INVESTIGATIONS

Repeated enflurane anaesthetics and model predictions: a study of the variability in the predictive performance measures 488
P. M. Vermeulen, J. G. C. Lerou, R. Dirksen, L. H. D. J. Booij and G. F. Borm

A physiological model of induction of anaesthesia with propofol in sheep. 1. Structure and estimation of variables 497
R. N. Upton and G. L. Ludbrook

A physiological model of induction of anaesthesia with propofol in sheep. 2. Model analysis and implications for dose requirements 505
G. L. Ludbrook and R. N. Upton

Overestimation of low cardiac output measured by thermodilution 514
J. P. Tournadre, D. Chassard and R. Muchada

Effect of temperature on the solubility of desflurane, sevoflurane, enflurane and halothane in blood 517
G. G. Lockwood, S. M. Sapsed-Byrne and M. A. Smith

Studies on the binding of $[^3H]$amethocaine to rat cerebrocortical membranes 521
T. Kudo, M. Kudo, K. Hirota and D. G. Lambert

Dissociation between the effect of nitrous oxide on spontaneous and reflexly evoked sympathetic activity in dogs 525
D. Ma, C. Wang, C. K. Pac-Soo, M. K. Chakrabarti and J. G. Whitwam

REVIEW ARTICLE

Anaesthesia for the surgery of emphysema 530
I. D. Conacher

SHORT COMMUNICATIONS

Granisetron reduces the incidence of nausea and vomiting after middle ear surgery 539
Y. Fujii, H Toyooka and H. Tanaka

Comparison between alfentanil, pethidine and placebo in the treatment of post-anaesthetic shivering 541
I. J. Wrench, G. Cavill, J. E. H. Ward and A. W. A. Crossley

CASE REPORT

Thermal softening of tracheal tubes: an unrecognized hazard of the Bair Hugger active patient warming system 543
J. L. Ayala and A. Coe

CORRESPONDENCE

Low-dose dopamine· there is a scientific rationale... 546
External cooling in critically ill febrile ICU patients 546
Inhaled nitric oxide 547
Predominant involvement of motor fibres in patients with critical illness polyneuropathy 547

BOOK REVIEWS

Applied Cardiovascular Physiology (Update in Intensive Care and Emergency Medicine Series) 549
Principles and Practice of Pharmacology for Anaesthetists, 3rd Edn 549

NOVEMBER

EDITORIALS: I "Walking extradurals" in labour: a step forward? 551
C. D. Elton, P. Ali and M. C. Mushambi
II Anaesthesia and the competence revolution 555
J. D. Greaves

CLINICAL INVESTIGATIONS

Pharmacokinetic and clinical study of ropivacaine and bupivacaine in women receiving extradural analgesia in labour 558
A. F. McCrae, P. Westerling and J. H. McClure

Magnetic resonance imaging of the extradural space of the thoracic spine 563
Y. Hirabayashi, K. Saitoh, H. Fukuda, T Igarashi, R. Shimizu and N. Seo

Pharmacokinetic–pharmacodynamic modelling of the EEG effects of Ro 48-6791, a new short-acting benzodiazepine, in young and elderly subjects 567
J. Dingemanse, J. Haussler, W. Hering, H. Ihmsen, S. Albrecht, M. Zell, H. Schwilden and J. Schuttler

Pharmacokinetics of midazolam given as an intranasal spray to adult surgical patients 575
S. Bjorkman, G. Rigemar and J. Idvall

Magnetic resonance spectroscopy of isoflurane kinetics in humans. Part I: elimination from the head 581
G. G. Lockwood, D. P. Dob, D. J. Bryant, J. A. Wilson, J. Sargentoni, S. M. Sapsed-Byrne, D. N. F. Harris and D. K Menon

Magnetic resonance spectroscopy of isoflurane kinetics in humans. Part II: functional localization... 586
G. G. Lockwood, D. P. Dob, D. J. Bryant, J A. Wilson, J. Sargentoni, S. M. Sapsed-Byrne, D. N. F. Harris and D. K. Menon

Differential effects of nitrous oxide and propofol on myogenic transcranial motor evoked responses during sufentanil anaesthesia 590
L. H. Ubags, C. R. Kalkman, H. D. Been and J. C. Drummond

Emergence times from xenon anaesthesia are independent of the duration of anaesthesia 595
T. Goto, H. Saito, Y. Nakata, S. Uezono, F. Ichinose and S. Morita

Effect of systemic N-methyl-D-aspartate receptor antagonist (dextromethorphan) on primary and secondary hyperalgesia in humans 600
S. Ilkjær, J. Dirks, J. Brennum, M. Wernberg and J. B. Dahl

Comparison of perioperative ketoprofen 2.0 mg kg^{-1} with 0.5 mg kg^{-1} i.v. in small children during adenoidectomy 606
E. Nikanne, H. Kokki and K. Tuovinen

Knee–chest *vs* horizontal side position during induction of spinal anaesthesia in patients undergoing lumbar disc surgery 609
E. Laakso, M. Pitkanen, J. Kytta and P. H Rosenberg

Pharmacokinetics of vecuronium during acute isovolaemic haemodilution 612
F. S. Xue, X. Liao, S. Y. Tong, J H. Liu, L. Li, Q. Zou and L. K. Luo

LABORATORY INVESTIGATIONS

Effects of volatile anaesthetics on spontaneous action potential firing of cerebellar Purkinje cells *in vitro* do not follow the Meyer–Overton rule 617
B. Antkowiak, H. Hentschke and K. Kirschfeld

Comparison of the effects of isoflurane with those of propofol on pulmonary vascular impedance in experimental embolic pulmonary hypertension 625
P. Ewalenko, S. Brimioulle, M. Delcroix, P. Lejeune and R. Naeije

Extra-pulmonary effects of inhaled nitric oxide in swine with and without phenylephrine 631
E. Troncy, M. Francœur, I. Salazkin, F. Yang, M. Charbonneau, G. Leclerc, P. Vinay and G. Blaise

Reduction in nitrogen dioxide concentration by soda lime preparations during simulated nitric oxide inhalation 641
J Weimann, J. U. Hagenah and J Motsch

REVIEW ARTICLE

Catalogue of human error 645
F. Arnstein

SHORT COMMUNICATIONS

Pre-emptive analgesia using local anaesthesia: a study in bilaterally symmetrical surgery 657
W. I. Campbell and R. W. Kendrick

Intra-articular morphine and clonidine produce comparable analgesia but the combination is not more effective 660
M. Gentili, P. Houssel, M. Osman, D. Henel, A. Juhel and F. Bonnet

Autotransfusion in major orthopaedic surgery: experience with 1785 patients 662
B. Borghi, E. Pignotti, M. Montebugnoli, A. Bassi, M. Corbascio, N. de Simone, K. Elmar, U Righi, A. M. Laguardia, S. Bugamelli, F. Cataldi, R. Ranocchi, M. A. Feoli, T. Bombardini, G. Gargioni, A. G. Franchini and G. C. Caroli

Continuous intra-arterial blood-gas monitoring in infants and children with cyanotic heart disease.. 665
M Hatherill, S. M. Tibby, A. Durward, V. Rajah and I. A. Murdoch

CASE REPORTS

Extradural catheter-related infections in patients with infected cutaneous wounds 668
M. Bengtsson, H. Nettelblad and F. Sjoberg

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 79, No.1 JULY 1997

EDITORIAL

Personal reflections

July 1997 marks the completion of my 10-yr term of office as Editor of the *British Journal of Anaesthesia*. Prior to 1987 I acted for 5 yr as the Editor of Educational Issues and was responsible for producing two issues of the Journal per year (normally January and July) devoted to review articles grouped into a single theme. In common with Dr Saidman, commenting in his final editorial on retirement from the editorship of *Anesthesiology*,[1] I also can state that these 15 yr have been one of the most enjoyable periods of my professional life, largely because of liaison with a diverse range of interesting and talented individuals, both scientists and clinicians, working in fields which extend beyond the boundaries of anaesthesia into basic sciences, community medicine and clinical laboratory disciplines. Furthermore, I have had the opportunity of collaborating with professional editors, publishers and experts in the printing industry. The insight, interest and opportunities provided by these contacts have compensated for the heavy workload of editing the Journal and being tied to the inexorable demands of monthly schedules.

In 1987, the *British Journal of Anaesthesia* published some 10 general issues per year and two postgraduate educational issues. The flow of manuscripts was such that each general issue contained of the order of 15–17 manuscripts per issue. There was a relatively long acceptance to publication interval and despite a modest submission rate of manuscripts, a full-time secretary was necessary as all material was processed manually in paper format. In 1987 my initial desire was to try to improve the interest for our readers by incorporating into every issue editorials, review articles, original articles, book reviews and correspondence. My intention in improving service to authors was to attempt to deal with all correspondence as expeditiously as possible, obtain rapid peer review assessments of high quality and achieve as low an acceptance to publication interval as possible.

With the manual system of handling all correspondence, improvements in many of these areas could be achieved only by computerization, and in 1991 a computerized database was installed in the office of the *British Journal of Anaesthesia*. This resulted in a dramatic improvement in the speed at which material could be processed and consequently, over the past 10 yr, the acceptance to publication interval for our Journal has diminished to almost 4 months; at the same time there has been a three-fold increase in the rate of submission of manuscripts to the Journal. Every issue since 1987 has carried at least one or two editorials. By reducing the number of postgraduate issues to one per year, it was thought that this would permit a free-standing review article to appear in each issue of the Journal, but this has not always been achieved.

An irritating trend over the past 10 yr has been the publication of several abstracting journals in which summaries of papers from the main peer-reviewed journals have been published together with a brief synopsis of the views of individuals. While this is acceptable competition in the free market economy, we would challenge the assertion of the supporters of these endeavours that it removes the necessity to read the original peer-reviewed articles. Brief overviews of original articles reflect the views of the individual composing that review and often such descriptions require interpretation in the light of any bias possessed by the reviewer, particularly when accompanied by a brief and personalized bibliography. The short synopsis should not however, be confused with the large review article (which has undergone peer review) published in this and other scientific journals where there is extensive referencing and a clear attempt to place all literature in a specific field into the appropriate perspective, often with the origination of new hypotheses.

The past 10 yr has also seen increased competition for the *British Journal of Anaesthesia* from the formation of other peer-reviewed specialist anaesthetic journals and the growth in size of the other general major anaesthetic journals. Despite these challenges, we have continued to attract high quality papers for publication; the *British Journal of Anaesthesia* has also grown in size and consequently we are now publishing of the order of 25 manuscripts per issue, almost double that in 1987, and our rejection rate has increased from approximately 45% to 60%.

There have been other major changes in the *British Journal of Anaesthesia* over the past 10 yr. In January 1990 the *BJA* became the official journal of the College of Anaesthetists and subsequently in 1992 the journal of the Royal College of Anaesthetists (RCA).[2] At the same time, in 1992, the Journal changed to the A4 format. Of the manuscripts submitted to the *BJA* in 1992, 40% originated from the UK, 29% from the remainder of Europe and 30% from the rest of the world. Between 1992 and 1996 there was a 20% increase in the number of manuscripts submitted, as a result of a 13% increase from Europe, 11% increase from the remainder of the world but a 4% decrease from the UK, despite our link with the RCA. To date, of the manuscripts accepted for publication from those submitted in 1996, 31% originated from the UK, 34% from elsewhere in Europe and 35% from the remainder of the world. The decrease in submission of articles from the UK provides evidence, I believe, of the severe problems in the UK affecting academic anaesthesia which I described in a recent editorial.[3]

This progressive and extensive change from a journal publishing material originating from the UK to one publishing predominantly from outside the UK has been accompanied by a broadening of the geographical origins of the membership of our editorial board, and the forging of collaborative links with *Anesthesia and Analgesia*, our US sister journal which was founded 1 yr before the *British Journal of Anaesthesia* and is currently celebrating its 75th anniversary.

Other major innovations in which the *BJA* has been involved include the development of the TEAL project. This CD-ROM incorporating 5 yr of articles from the four leading anaesthetic journals in the world has unquestionably been an outstanding success and annual meetings of all four editors-in-chief will continue to maintain the momentum in improving and extending this service to the benefit of our readers.

Although computerization of our database handling system has enabled the Journal to grow without an increase in secretarial input, the same is not true of the editorial arrangements. Until 1997, the Journal was managed largely by an editor with the assistance of two associate editors. However, commencing in July 1997 the new Editor-in-Chief, Dr Jennifer Hunter, will be assisted by a panel of four section editors, who will look after specific sub-specialties in anaesthesia.

Because of the long interval between submission of manuscripts and publication and the 4-month interval between acceptance and publication, there will be a change-over period during which both Dr Hunter and myself will act as Editors-in-Chief from July 1997 to January 1998 and thereafter my involvement will cease. It should be noted that from June 1997, all new manuscripts and new letters to the editor should be sent to Dr Hunter.

The task of editing the *BJA* would be impossible without the support and advice of the editorial board and assistance from a large panel of manuscript reviewers. These individuals, who are inevitably busy and committed professionals, fulfil a demanding task; perhaps only an editor can truly appreciate the dedication and effort involved.

Despite this aid, the new Editor-in-Chief will continue to face problems in producing a high quality scientific journal. It seems inevitable but unfortunate that there will continue to be a growth in the number of journals, both subscription and sponsored, and also an increase in the number of articles being presented to the *BJA* for possible publication, although as noted elsewhere by Greene,[4] this will not necessarily be accompanied by a parallel improvement in quality. However, I have no doubt that while it may not be possible to detect an improvement in scientific quality within a period of a few years, quinquennial comparisons reveal a steady and continuous improvement in the scientific quality of what is published in the *BJA*. Furthermore, I have been delighted by the improvement in the standard of English composition in articles accepted for publication from countries where the native language is not English, although this does not apply to many that are rejected. This change has been so great since 1987 that the extent of subediting required now differs little from that required for manuscripts emanating from the UK and North America. I am grateful to all authors for preferring the *BJA* to other journals and for their work in meeting our requirements for submission of manuscripts

It is important that the increase in workload for our Journal does not place too great an imposition on individual assessors, which is a problem as the increase in specialization of manuscripts renders it difficult to maintain a large panel of assessors with the necessary degree of expertise in the appropriate area. In addition, while there has not, to our knowledge, been any documented case of fraudulent material published in the *British Journal of Anaesthesia*, recent events in other specialist journals suggest that increased vigilance is necessary on the part of both the editorial team and assessors to safeguard against this problem. I am confident that the new editorial team will respond to all of these challenges and that the *BJA* will continue to retain its place among the leading journals of anaesthesia.

CLINICAL INVESTIGATIONS

Ropivacaine 0.75% for extradural anaesthesia in elective Caesarean section: an open clinical and pharmacokinetic study in mother and neonate

C. P. J. Morton, S. Bloomfield, A. Magnusson, H. Jozwiak and J. H. McClure

Summary

In an open study we have investigated the efficacy of 20 ml of 0.75% ropivacaine (7.5 mg ml^{-1}) to provide extradural anaesthesia for elective Caesarean section. Plasma concentrations (total and free) were estimated in the mother and neonate. Anaesthesia was effective and safe. Plasma concentrations of ropivacaine in the mother and neonate were within safe limits and consistent with previous studies. Two mothers received accidental i.v. injections of ropivacaine 75 mg and 150 mg, respectively, without serious adverse effects. (*Br. J. Anaesth.* 1997; **79**: 3–8).

Key words
Anaesthesia, obstetric. Anaesthetic techniques, extradural. Anaesthetics local, ropivacaine. Pharmacokinetics, ropivacaine

Ropivacaine (1-propyl-2', 6' pipecoloxylidide hydrochloride monohydrate) is a new, long-acting, amide-type local anaesthetic which has a chemical structure similar to that of bupivacaine, the butyl group being replaced by a propyl group. It differs also in that it is prepared as the pure S isomer rather than as a racemic mixture. *In vivo* animal studies have suggested that central administration of both drugs produces similar patterns of onset and extent of sensory and motor block, but that ropivacaine has a shorter duration of action[1] and causes less motor block.[2] In humans, extradural administration of ropivacaine produces sensory block similar to that produced by the same volume and concentration of bupivacaine, but motor block is slower in onset, shorter in duration and less intense.[3] In addition, ropivacaine at similar plasma concentrations is less cardiotoxic in both animals[4] and humans.[5]

The advantages of extradural, rather than general, anaesthesia for mother[6] and baby[7] for Caesarean section are well documented. However, onset time is relatively slow, block may sometimes be patchy, asymmetrical or limited in extent, and visceral pain may be experienced by up to 50% of patients.[8] Bupivacaine 0.75% has been said to approach the ideal for a single agent for extradural anaesthesia for Caesarean section[9] but fears of toxicity led to withdrawal of its approval for use in obstetrics. An agent of similar potency to, but less toxicity than, 0.75% bupivacaine could be a useful alternative to the drugs currently available for extradural anaesthesia for Caesarean section.

The objectives of this study were to investigate the efficacy of 0.75% ropivacaine 20 ml to provide extradural anaesthesia for Caesarean section, to determine the effect of this dose of ropivacaine on the neonate, to measure the maximum total plasma concentration of ropivacaine in the mother, and total and free concentrations of ropivacaine in umbilical and maternal veins at delivery. An open design was chosen because 0.75% ropivacaine had not been used before in obstetric anaesthesia.

Patients and methods

Thirty-eight women (ASA I and II) carrying a full term ($\geq$37 weeks) singleton fetus undergoing elective Caesarean section under extradural anaesthesia gave informed consent to the study which was approved by the hospital Ethics Committee. Women with diabetes, placenta praevia, pregnancy-induced hypertension or carrying a baby judged small for dates were excluded, as were those with a history of substance or alcohol abuse. Other reasons for exclusion were height less than 152 cm or weight more than 100 kg.

Premedication comprised ranitidine 150 mg the night before and 2 h before operation. On arrival in the anaesthetic room maternal heart rate and arterial pressure were recorded, a cardiotocograph attached and 30 ml of sodium citrate 0.3 mol $litre^{-1}$ given orally. Hartmann's solution 1 litre was administered i.v. while the extradural catheter was inserted and the block established.

After infiltration of the skin with lignocaine, a 16-gauge Tuohy needle was inserted into the extradural space via the first or second lumbar interspace using a midline approach and loss of resistance to saline. A lateral eyed extradural catheter was inserted 3–4 cm in a cephalad direction, the catheter taped in place

Accepted for publication. March 18, 1997

and the mother turned to the wedged supine position. Provided that neither blood nor CSF were obtained on aspiration, 0.75% ropivacaine 3 ml were injected as a test dose. Five minutes after the end of the test dose, in the absence of signs of intravascular or intrathecal injection, 0.75% ropivacaine 17 ml were injected incrementally over 2 min.

Loss of sensation to pinprick (27-gauge short-bevel needle) was assessed at 5-min intervals for 30 min, and at 45 min and 60 min. At 60 min only the upper sensory level was assessed because surgery had already started. Motor block was assessed, at the same times, according to a modified Bromage scale (0=no motor block, 1=inability to raise extended leg (just able to move knee), 2=inability to flex knee (able to move foot only), 3=inability to flex ankle joint (unable to move foot or knee)). Surgery was not started unless there was bilateral loss of sensation to pinprick from T6 to S3; if this had not been achieved at 45 min, 5-ml increments of 2% lignocaine with adrenaline 1 in 200 000 were given and the patient withdrawn from further efficacy assessments. After operation sensory levels and motor block were assessed at 30-min intervals until return of normal sensation and motor power.

Pain on skin incision, quality of analgesia, as judged by the patient and anaesthetist, and quality of neuromuscular block, as judged by the obstetrician, were recorded. Times from skin incision to uterine incision, and uterine incision to delivery, and whether or not the uterus was exteriorized were noted.

Maternal heart rate and arterial pressure were measured at 3-min intervals from the end of the test dose until the end of surgery. Fetal heart rate was measured continuously until the start of surgery. After surgery maternal heart rate, arterial pressure, upper and lower sensory levels and motor power were measured at 30-min intervals until the block had regressed.

Evaluation of the newborn was performed by Apgar score at 1 and 5 min after birth and by neurological and adaptive capacity score (NACS)[10] at 2 h and 24 h after delivery.

Adverse events occurring from the start of anaesthesia to discharge from hospital, either observed by attending staff or reported by the patient in response to standard questions, were recorded. Apart from treatment of pain during extradural block, which was specified in the design, decisions on management of adverse events were made by the appropriate clinical staff. A telephone call enquiring after the mother and baby was made 2–3 weeks after discharge.

Maternal blood samples were obtained from a peripheral vein immediately before administration of the test dose, at the end of extradural injection, at 10-min intervals for 60 min and at delivery. A sample of umbilical venous blood was obtained after the cord was clamped. Samples of maternal and umbilical venous blood were obtained at delivery and pH was measured immediately on the labour ward (Instrumentation Laboratories); all other blood samples were centrifuged at 3000 rpm for 10 min, the plasma withdrawn and then frozen. Samples were analysed at the end of the study by the Department of Bioanalysis, Astra Pain Control AB, Södertälje, Sweden. Total concentrations of ropivacaine were measured using gas chromatography with a nitrogen sensitive detector[11] and free concentrations were measured by coupled column liquid chromatography after ultrafiltration of the plasma samples.[12] For total concentrations the limit of quantification was set at 0.008 mg litre^{-1} and interassay precision was 2.5–5.7% in the concentration range 0.027–1.141 mg litre^{-1}. For free concentrations the limit of quantification was set at 0.003 mg litre^{-1} and interassay precision was 2.1–8.4% at a concentration of 0.026 mg litre^{-1}. Recovery was close to 100% for both assays. Alpha$_1$-acid glycoprotein (AAG) concentrations were measured by a radioimmunodiffusion procedure.[13]

The following measurements were made: (1) maternal samples: total ropivacaine concentration immediately before the test dose, at the end of extradural injection, at 10-min intervals for 60 min and at delivery; free ropivacaine concentration immediately before the test dose, at 20 min and at delivery; AAG concentration immediately before the test dose, and at delivery; and (2) umbilical vein samples: total and free ropivacaine concentration and AAG concentration.

Results

Seven patients were excluded from efficacy analysis because of technical failure or study violation (including two patients who received accidental i.v. injections of ropivacaine). In addition, one patient with poor venous access declined to have an i.v. cannula sited for blood sampling and samples for one patient were not frozen. Therefore, results from 31 patients were valid for analysis of efficacy and 29 for pharmacokinetic analysis. All patients who received ropivacaine were followed-up with respect to safety. The characteristics of the 31 patients included in the study are shown in table 1.

Table 1 Patient characteristics (31 patients) (mean (SD) [range])

Age (yr)	29.8 [23–44]
Height (cm)	162 (6.0) [152–173]
Weight (kg)	72.5 (8.9) [54–91]

SENSORY BLOCK

Twenty-six of the 31 patients (84%) had a sensory block to pinprick from T6 to S3 (which was defined as adequate for surgery) at 45 min. Four patients required increments of 2% lignocaine with adrenaline 1 in 200 000 to achieve adequate block; one of these had surgery delayed because the obstetric staff were required urgently elsewhere and eventually underwent Caesarean section under subarachnoid block. These four patients, together with one patient who did not develop a block below L4, were not included in the analysis of duration of motor and sensory block. Times to onset and duration of sensory block at various dermatomes are shown in table 2.

Table 2 Times to onset (min) and duration (h) of sensory and motor block (31 patients)

	Onset			Duration		
	Median	Quartiles	Range	Median	Quartiles	Range
Sensory block						
S3	23	15, 28	13–40	4.1	3.1, 5.9	2.0–7.7

L5	15	13, 23	5–45	4.5	3.3, 5.5	2.1–7.6
L3	10	8, 15	5–25	4.3	3.4, 5.4	2.4–7.1
L1	5	5, 10	5–13	4.3	4.0, 5.3	1.9–7.1
T12	8	5, 10	5–13	4.4	4.1, 5.3	1.9–6.6
T10	10	8, 15	5–38	4.4	3.9, 4.7	2.8–6.5
T8	13	10, 15	5–35	3.7	3.3, 4.6	1.8–6.0
T6	15	13, 20	5–38	3.4	2.6, 3.9	1.3–5.8
Motor block						
Grade I	18	13, 25	6–45	2.2	1.8, 3.1	1.3–5.1
Grade II	26	20, 30	11–45	1.7	1.5, 3.4	1.3–4.2
Grade III	25	25, 38	20–45	1.6	1.4, 2.5	1.1–3.7

MOTOR BLOCK

Of the 31 patients who were eligible for efficacy assessment, grade I motor block developed in 30 (97%) patients, grade II in 16 (52%) and grade III in 11 (35%), at 45 min. Times to onset and duration are shown in table 2. Sensory block outlasted motor block by a median time of 2 h 30 min (range 1 h 15 min to 5 h 30 min).

SURGERY

Duration of the different stages of anaesthesia and surgery are shown in table 3. Although many patients had a block adequate for surgery within 25 min (table 2) the study design did not permit surgery to start until 45 min after the start of extradural injection. In addition, further delay sometimes occurred because the operating theatre was in use.

No patient reported pain on skin incision. The quality of anaesthesia was judged as excellent or good by the patient and satisfactory by the anaesthetist in 25 of the 26 patients (96%) who were eligible for efficacy assessment, although 10 patients (39%) reported vague symptoms suggestive of incomplete visceral block. In one case quality of anaesthesia was judged to be poor by the patient and unsatisfactory by the anaesthetist. This patient, who had an adequate somatic block, reported severe visceral pain and required i.v. morphine when her uterus was exteriorized for suturing. Quality of abdominal wall muscle relaxation was judged adequate by the obstetrician in all 26 patients.

CARDIOVASCULAR EFFECTS

There was a mean decrease in maternal systolic and diastolic arterial pressures of 15% from baseline in the first 30 min; maternal heart rate was stable. Treatment of hypotension was left to the discretion of the anaesthetist; 25 of 31 patients were treated with ephedrine. Fetal heart rate was stable in all but three babies. In two of these fetal bradycardia was associated with maternal hypotension and both reverted to a satisfactory rate when the mothers were turned on their left side and hypotension was corrected. In the third, an unexplained fetal tachycardia resolved spontaneously after 3 min without specific action being taken.

NEONATAL ASSESSMENTS

Umbilical vein pH was normal (7.25–7.5) in all but one baby. In this case umbilical vein pH was 7.1 and concurrent maternal vein pH was 7.29; repeat measurement of maternal vein blood revealed a pH of 7.45. The baby was vigorous at birth with Apgar scores of 7 and 10, therefore the low values were attributed to machine measurement error. The pH of maternal vein blood was normal (7.35–7.45) in all but three other mothers in whom the abnormality was slight (pH 7.32–7.34).

Thirty neonates had an Apgar score of 7 or more at 1 min and all had a score of 9 or 10 at 5 min. NACS at 2 and 24 h are shown in table 4.

ACCIDENTAL I.V. INJECTION OF ROPIVACAINE

Two patients received accidental i.v. injections of ropivacaine. In both cases the test dose of 22.5 mg (3 ml) of ropivacaine had been uneventful. The first patient received another 7 ml of 0.75% ropivacaine before developing unequivocal symptoms of i.v. local anaesthetic. The injection was stopped, the extradural catheter resited and another 3+17 ml of 0.75% ropivacaine injected. Blood samples were

24 h	31	0	0	2	0	2	5	8	7	5	2

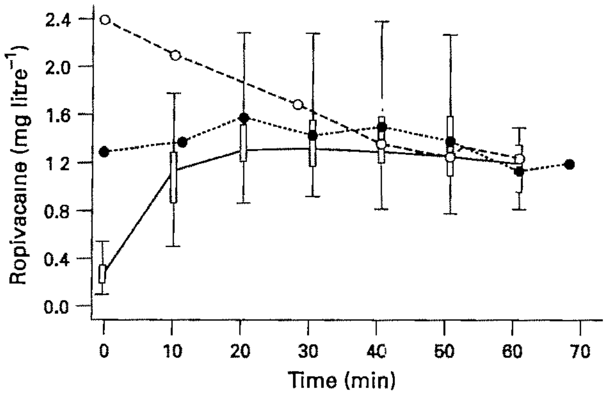

Figure 1 Total plasma concentration of ropivacaine after administration of ropivacaine 150 mg i.v. (○) and extradural ropivacaine 150 mg administered 28 min after ropivacaine 75 mg i.v. (●). For comparison, the data from the patients (n=28) who received extradural ropivacaine 150 mg are shown by the box and whisker plot. Median values are connected; box is first and third quartiles, whiskers are maximum and minimum values.

obtained after the end of the second 17-ml extradural injection and at 10-min intervals thereafter. The second patient received approximately the same dose of ropivacaine before developing symptoms mildly suggestive of i.v. injection. The symptoms resolved quickly when the injection was stopped, and did not recur until the entire 20 ml of 0.75% ropivacaine had been injected. Blood samples were obtained as soon as the extradural injection had finished and at 10-min intervals thereafter. Plasma concentrations in these two patients, compared with plasma concentrations in patients who received uneventful extradural anaesthesia are shown in figure 1.

MISCELLANEOUS EVENTS

One baby was considered to have transient tachypnoea of the newborn. One baby had a small midline gum defect and one required surgery for pyloric stenosis some weeks after discharge. One baby was reluctant to breast feed for 4 days but fed satisfactorily when bottle feeding was started. One baby was reported to vomit after feeds throughout the study. When followed-up 6 weeks after discharge, he was still vomiting occasionally but gaining weight.

In the period between leaving the recovery room and discharge from hospital, one mother reported backache and two reported leg pain. No mother complained of residual effects of extradural anaesthesia or the technique at follow-up by telephone 2–3 weeks after delivery.

PHARMACOKINETICS

In addition to the nine patients excluded from pharmacokinetic analysis, five individual blood samples from four other patients were excluded because of handling errors. Valid results were available from 29 patients (table 5). Mean maximum maternal ropivacaine concentration ($C_p$max) was 1.47 (SD 0.28) mg litre^{-1}, occurring at a mean time (tC_pmax) of 40 (13) min after extradural injection. At the time of delivery, mean umbilical vein concentrations were: total 0.37 (SD 0.18) mg litre^{-1}; free 0.06 (0.015) mg litre^{-1}. Mean umbilical vein/maternal vein (UV/MV) ratios for total and free concentrations were 31 (17) % and 74 (16) %, respectively. Mean free fraction (fu) in the neonates (0.18 (0.06)) was greater than in mothers (0.07 (0.02)).

Table 5 Maximum total concentration of ropivacaine ($C_p$max), time to $C_p$max (tC_pmax, total (C) and free (Cu) concentrations of ropivacaine, and alpha$_1$ acid glycoprotein (AAG) concentrations in maternal and umbilical (UV) veins at specified times (n=9)

Discussion

The open design of this study prevents a true comparison of ropivacaine with other agents for extradural anaesthesia in Caesarean section. The majority (84%) of our patients had a block adequate for surgery after extradural administration of 20 ml of 0.75% ropivacaine. Twenty-five of these patients (96%) assessed their anaesthesia as good or excellent. All patients had neuromuscular block that was adequate for surgery. Noble and others,[14] in a study from the same centre, assessing adjuncts to extradural bupivacaine for Caesarean section, reported that 37 of 42 (88%) patients had a block adequate for surgery after 20 ml of 0.45% bupivacaine (with adrenaline 5 μg ml^{-1}, fentanyl 100 μg, or both) and 83% rated analgesia as good or excellent. However, 49% of their patients required supplementation during surgery, compared with one of 26 in our study.

Norton, Davis and Spicer[15] compared 16–20 ml of 0.5% bupivacaine with 2% lignocaine with adrenaline; 25% of patients required supplementary local anaesthetic to achieve bilateral block to T6. The procedure was pain free in only 53% of patients and 12% reported discomfort that was distressing. In a large retrospective clinical review, Crawford, Davies and Lewis[16] reported that approximately 12% of patients undergoing Caesarean section under extradural anaesthesia required some form of supplementation to their original block.

It was notable that we found marked separation between the offset of motor and sensory block. Theoretically this should provide analgesia for some hours after return of motor function but in some patients sensation returned in the area of the surgical incision at a relatively early stage. Comparison of motor block with that reported in other studies is difficult because of the potential for observer variation.

The cardiovascular effects were those expected of extensive extradural block in mothers at full term.

Umbilical vein pH, used as a measure of adequate placental perfusion, was normal in all but one case, in whom maternal venous pH was also decreased. These results were not consistent with the clinical condition of either the mother or baby and as repeat measurement of maternal venous pH was normal, the results were considered to be spurious. Only two babies had an unsatisfactory Apgar score at 1 min; both improved rapidly after oxygen therapy. All babies had satisfactory Apgar scores at 5 min.

The neurological and adaptive capacity scoring (NACS) system[10] was devised as a scoring test to differentiate between the more generalized neurological depression associated with drugs and anaesthesia, and that associated with asphyxia or birth trauma in term infants (≥37 weeks). A score of 35 or greater indicates a neurologically vigorous neonate. In our study, 20 of 30 babies at 2 h and four of 31 at 24 h had a score of less than 35. However, there was no control group for comparison.

Ropivacaine 0.5% has been compared with 0.5% bupivacaine for extradural anaesthesia for elective Caesarean section.[17] There were no differences between the two drugs in terms of cardiovascular effects or profile of sensory block. Time of onset and intensity of motor block were the same but duration of motor block was less with ropivacaine. There was no difference in neonatal outcome as assessed by Apgar score, umbilical cord blood-gas tensions or NACS at 2 and 24 h.

One baby in our study was admitted to the special care baby unit suffering from transient tachypnoea of the newborn. This baby's mother had received a higher dose of ropivacaine than intended (225 mg, of which 75 mg was given i.v.). Transient tachypnoea of the newborn is attributed to delay in resorption of fetal lung fluid after delivery and is characterized by tachypnoea and increased oxygen requirements. The incidence after delivery by elective Caesarean section is approximately 9%. The chest wall is not subject to the forces experienced in vaginal delivery and thoracic gas volume is less. Most infants recover in 2–3 days, as was the case in this neonate and there were no long-term sequelae. Neither transient tachypnoea of the newborn nor the other miscellaneous events were thought to be related to ropivacaine.

With the exception of the two women who received accidental i.v. injections there were no maternal symptoms attributable to central nervous system (CNS) local anaesthetic toxicity. Scott and colleagues[5] reported early mild symptoms of CNS toxicity at venous plasma concentrations of ropivacaine of 1–2 mg litre^{-1}. However, the subjects in that study received i.v. infusions of ropivacaine 10 mg min^{-1} and symptoms occurred within 15 min of the start of infusion. In an earlier study the same author[18] reported that toxicity occurred at lower peak plasma concentrations during rapid, compared with slow, infusion of local anaesthetic. The rate of increase and absolute value of plasma concentration was considered to influence the development of toxicity.

The test dose of 3 ml of 0.75% ropivacaine in our study failed to predict intravascular catheter placement on the two occasions that accidental i.v. injection occurred. On these occasions symptoms of i.v. local anaesthetic did not occur until another 7 ml of 0.75% ropivacaine (52.5 mg) had been injected. In one patient the symptoms were so equivocal that the injection was restarted when her symptoms resolved and it was not until the injection was completed that symptoms returned. This patient, who received a total of 150 mg of ropivacaine i.v. had no obvious effects other than failure to develop a block.

The time to maximum plasma concentration and its variability in this study were almost identical to those in a previous study[19] of the same dose of extradural ropivacaine in non pregnant patients but the $C_P$max value in our study was greater and more widely distributed. This is consistent with a study in sheep[20] which demonstrated slower clearance of ropivacaine during pregnancy.

Local anaesthetics are small molecules which, when unionized, are lipid soluble. The unbound, free portion crosses the placenta readily, and at equilibrium the free concentration is the same in the mother and neonate.[21 22] In the fetal circulation equilibrium occurs between the bound and unbound local anaesthetic. Plasma concentration of AAG, to which ropivacaine is bound extensively, is less in the neonate than in the mother, therefore total plasma concentration of ropivacaine is less in the neonate than in the mother, but the free fraction is greater.

In our study mean $C_P$max occurred before delivery and therefore maternal plasma ropivacaine concentration was declining at the time of delivery. At this time Cu (UV) was less than Cu (maternal vein), implying that equilibrium between maternal and fetal circulations had not been achieved.

In summary, 20 ml of 0.75% ropivacaine provided safe and effective extradural anaesthesia for Caesarean section. The commonest side effect was hypotension, consistent with extradural block. Two patients tolerated accidental i.v. injection of ropivacaine (75 mg and 150 mg, respectively), reporting only early symptoms of toxicity. There were no other adverse events attributable to systemic local anaesthetic toxicity. Maternal and umbilical vein ropivacaine concentrations were within safe limits. The test dose of 3 ml of 0.75% ropivacaine was unreliable in detecting intravascular catheter placement.

Serum concentrations of bupivacaine during prolonged continuous paravertebral infusion in young infants

S. L. W. CHEUNG, P. D. BOOKER, R. FRANKS AND M. POZZI

Summary

We have studied the efficacy of prolonged, continuous paravertebral infusion of bupivacaine for the management of post-thoracotomy pain in 22 infants with a median age of 1.5 weeks (range 1 day to 20.4 weeks). Immediately before chest closure, 0.25% bupivacaine 1.25 mg kg^{-1} was given into an extrapleural paravertebral catheter, inserted under direct vision. Subsequently, 0.125% bupivacaine with adrenaline 1:400 000 was infused at a rate of 0.2 ml kg^{-1} h^{-1} for 48 h. We confirmed that extrapleural paravertebral catheter placement under direct vision was easy in neonates and infants. The technique provided effective postoperative pain relief in 86% of patients, with three patients requiring morphine in addition. Mean serum concentration of bupivacaine after 48 h was 1.60 (0.67) μg ml^{-1}, but bupivacaine concentrations >3 μg ml^{-1} were found in three patients at 30–48 h. There were no major complications relating to the technique, and paravertebral block was an effective method of providing prolonged post-thoracotomy analgesia in these young infants. (*Br. J. Anaesth.* 1997; **79**: 9–13).

Key words

Anaesthetic techniques, regional, paravertebral. Anaesthetics local, bupivacaine. Anaesthesia, paediatric. Pain, postoperative. Surgery, thoracic. Infants.

Regional analgesia has become a routine part of the perioperative management of children undergoing thoracic surgery, with both paravertebral[1] and intrapleural[2] infusions of bupivacaine being advocated. However, we believe that paravertebral blocks are inherently safer for small infants because the local anaesthetic is applied more directly onto the appropriate nerve roots and the total drug dose required to provide effective analgesia should be lower than that using the less direct intrapleural approach. Nevertheless, in our previous study of 20 infants receiving an infusion of 0.25% bupivacaine 0.5 mg kg^{-1} h^{-1} into the paravertebral space for 24 h, we found significant cumulation of bupivacaine in some patients and maximum serum bupivacaine concentrations approached potentially toxic levels.[1]

We hypothesized that the safe duration of postoperative analgesia that could be offered using this technique may be prolonged by reducing the amount of bupivacaine being administered. Furthermore, we hoped that addition of a low concentration of adrenaline to the solution would restrict systemic absorption and thus reduce toxicity potential. The addition of adrenaline to bupivacaine, given by continuous extradural infusion to young children, has been shown to produce significant prolongation of analgesic effect.[3] Therefore, we assessed the analgesic efficacy and measured intermittently serum concentrations of bupivacaine, during infusion of bupivacaine 0.25 mg kg^{-1} h^{-1} with adrenaline 1:400 000 for 48 h, into a paravertebral catheter in infants requiring thoracotomy.

Patients and methods

The study was approved by the local Ethics Committee and written, informed parental consent was obtained. We studied 22 infants, >37 to <60 weeks gestational age (neonates included), who were >2.0 kg in weight, undergoing elective or emergency thoracotomy for various cardiac procedures.

For 14 infants no premedication was prescribed. I.v. cannulation was performed before anaesthesia which was induced with thiopentone 4 mg kg^{-1}. Atracurium 0.5 mg kg^{-1} was used to facilitate tracheal intubation. The remaining eight patients had required preoperative artificial ventilation and an i.v. infusion of morphine 10–20 μg kg^{-1} h^{-1}, the latter being stopped after induction of anaesthesia. For all patients anaesthesia was maintained subsequently with 0.5% isoflurane and 50–66% nitrous oxide in oxygen, and fentanyl 2 μg kg^{-1} i.v. was used to provide peroperative analgesia. Repeated injections of atracurium 0.25 mg kg^{-1} were given as necessary to maintain neuromuscular block. Intra-arterial and central venous cannulation were used to facilitate arterial pressure monitoring and blood sampling for bupivacaine assays. A blood sample was also obtained after induction of anaesthesia for baseline measurement of serum bupivacaine concentration (zero control).

When the surgical procedure was completed, just before chest closure, the parietal pleura was peeled medially starting at the thoracotomy space. The resulting pocket was extended from the posterior wound margin onto the vertebral bodies and for two intercostal spaces above and below using a Lahey's forceps to create a tunnel in the paravertebral space. A Tuohy needle was inserted percutaneously at a site close to the angle of the rib, near the incision, to emerge near the extrapleural pocket created earlier. The stylet was removed and a side holed (od 0.9 mm) extradural catheter (Minipack, Portex Ltd) was advanced through the needle and positioned cranially under direct vision such that approximately 3 cm of its length lay against the costo-vertebral joints within the pocket, as described previously.[1] The needle was removed and the parietal pleura was re-attached, along the posterior edge of the wound, before the thorax was closed. The catheter was aspirated and a test dose of 0.125% bupivacaine 1.0–1.5 ml with adrenaline 1:400 000 was administered through a bacterial filter. If haemodynamic variables remained stable, a loading dose of 0.25% bupivacaine 0.5 ml kg^{-1} (1.25 mg kg^{-1}) was injected into the catheter over 1 min. An infusion of 0.125% bupivacaine with adrenaline 1:400 000 at a rate of 0.2 ml kg^{-1} h^{-1} (0.25 mg kg^{-1} h^{-1}) was then started and continued for 48 h at the same rate.

All patients were nursed after operation in the ICU and the trachea was extubated when spontaneous ventilation was deemed adequate and there were no medical or surgical contraindications. Before extubation, a simplified CRIES pain score[4], excluding the crying variable, was performed by an ICU nurse as part of the routine hourly observations. When the trachea was extubated, assessments of postoperative pain were made using the full CRIES pain scale, although throughout the study the scoring for "requirement for oxygen" was modified such that the expected (baseline) oxygen saturation achieved during anaesthesia after surgery, with 30–50% oxygen, was used to assess subsequent *changes* in oxygen requirements required to achieve this baseline level. In the first 24 h after operation an i.v. infusion of morphine 10 μg kg^{-1} h^{-1} was prescribed as "rescue analgesia" but given only if a pain score >3/10 was observed and could not be reduced by a dummy or feeding. Every patient was given paracetamol 15 mg kg^{-1} via a nasogastric tube, every 6 h, from 24 to 72 h after operation.

Blood samples were obtained from a central venous or arterial cannula at 6-hourly intervals after starting the infusion, for subsequent measurement of serum concentrations of bupivacaine. An additional sample was obtained 6 h after stopping the infusion. Blood samples were centrifuged, serum separated and stored at −20 °C before assay. Serum concentrations of bupivacaine were measured by reverse phase high pressure liquid chromatography, as described previously.[1]

Results

Patient age, weight and operations are shown in table 1. Median age was 1.5 (0.1–20.4) weeks and median weight 3.2 (2.5–5.5) kg. Insertion of the extradural paravertebral catheter was not technically difficult, even in the smallest neonate. There were no major complications or adverse haemodynamic effects related to either catheter insertion or production of paravertebral block in any patient. Two patients had significant leakage of pleural fluid at the skin entry point of the paravertebral catheter, without compromise to analgesia. Another two patients had transient, accidental disconnection of the infusion. In seven babies the trachea was extubated within 1 h of surgery; in the other 15 babies the trachea remained intubated (without paralysis) for a median time of 24.0 (3–48) h after surgery.

48	1.60 (0.67)
54	0.88 (0.44)

complications. In 18 patients the median mean hourly pain score was 0.29 (0.00–1.63); three patients had pain scores >3/10 and required morphine as rescue analgesia soon after operation. In one of these three patients a short period of accidental disconnection was associated with low bupivacaine concentrations. A second patient was subsequently diagnosed, by endoscopy, to have had severe gastritis. There was no obvious reason why the block did not work in the third patient.

Technical problems prevented sampling in one patient. There was a progressive increase in serum bupivacaine concentrations during the infusion period in most patients (fig. 1). Mean serum bupivacaine concentrations measured during the infusion period demonstrated wide variation between patients (table 2). Mean maximum serum bupivacaine concentration measured at any time after starting the infusion was 1.65 (0.47) μg ml^{-1} in 18 of 21 patients. Three patients had maximum bupivacaine concentrations of 3.29, 3.14 and 3.21 μg ml^{-1} at 30, 42 and 48 h, respectively. No patient exhibited clinical signs suggestive of bupivacaine toxicity.

Discussion

We have confirmed that direct placement of a paravertebral catheter at the time of a thoracotomy was simple, even in small neonates. Continuous infusion of bupivacaine into the catheter provided good analgesia in the great majority of patients for 48 h after operation. However, the analgesic efficacy of the technique was slightly less than that found in our previous study, where we used a higher dose of bupivacaine.[1] Four patients (18.2%) required morphine as additional analgesia during the early postoperative period, although one of these received morphine not because of block failure but because of surgical complications requiring immediate intervention.

The highest serum bupivacaine concentration reported in our previous study of similar aged infants, using an infusion of bupivacaine 0.5 mg kg^{-1} h^{-1} for 24 h, was 3.14 μg ml^{-1}, with a mean maximum concentration of 2.0 μg ml^{-1}.[1] We believe that these bupivacaine concentrations are potentially toxic[5–10] and, as we wished to provide effective analgesia for at least 48 h without undue risk, we used an infusion at half the original drug concentration, although with the same infusion rate, and with the addition of adrenaline. This new dosage regimen is similar to that suggested for caudal extradural analgesia in infants.[11] We used the same loading dose of 0.25% bupivacaine as in our previous study (1.25 mg kg^{-1}), as we know that this dose does not lead to dangerously high concentrations (mean peak 1.03 (0.56) μg ml^{-1}). Furthermore, this volume of solution (0.5 ml kg^{-1}) appears necessary to cover reliably at least five intercostal segments, which is usually required for adequate post-thoracotomy analgesia.[12] In this study the reduced bupivacaine dosage resulted in maximum serum concentrations that were well below potentially toxic concentrations in 18 infants. However, in three patients bupivacaine concentrations >3 μg ml^{-1} were measured at 30–42 h of infusion. One of the three patients with high bupivacaine concentrations required additional analgesia soon after surgery and perhaps exceptional vascularity of the paravertebral space, resulting in increased systemic absorption, may help explain these unexpected findings. It would appear, therefore, that prolonged infusion of bupivacaine for >30 h in young infants may result in high serum bupivacaine concentrations in a small, but unpredictable, proportion. However, the normal postoperative increase in plasma α_1-acid glycoprotein (AAG) concentration[13] may limit the potential toxicity of accumulating total bupivacaine by limiting the free bupivacaine concentration.[14]

However, the relationship between plasma AAG concentration, unbound bupivacaine concentration and toxicity is more complex than is immediately apparent.[14–17] Bupivacaine has a large volume of distribution (approximately 2.5 litre kg^{-1}).[18] Under conditions of near steady state, as when systemic drug absorption is gradual during bupivacaine infusion into the paravertebral space, only a small fraction of total drug dose is confined to the blood. Under these conditions, changes in AAG concentrations may have little impact on toxicity as plasma protein binding does not control access of drug to sites of toxicity.[14] Furthermore, for drugs such as bupivacaine which have a low hepatic extraction ratio, any increase in free drug concentration may be compensated by faster elimination.

Significant differences between arterial and venous local anaesthetic concentrations have been shown within the first hour of a laryngeal spray[19] or single caudal,[20] extradural[21] or intercostal injection.[21 22] This occurs because the lung *temporarily* sequestrates a large quantity of the local anaesthetic, because of a high lung–blood coefficient, before subsequent release.[16] It follows that patients with intracardiac right-to-left shunts may be at higher risk of CNS toxicity than normal patients, after accidental i.v. injection of bupivacaine. Animal experimental work has supported this premise.[23 24] However, in our study, in all patients with significant right-to-left intracardiac shunting, pulmonary blood flow was at least partially restored by the formation of a subclavian artery–pulmonary artery shunt. More importantly, however, in all of the studies mentioned above reporting simultaneous arterial and venous local anaesthetic concentrations, arterio-venous differences had become insignificant by 30–60 min after injection. In our study, we have postulated that by the time of the first sample at 6 h, near steady state conditions prevailed, and any difference between arterial and central venous bupivacaine concentrations would be insignificant.

Bupivacaine binds to erythrocytic components and also plasma proteins, and the blood–plasma bupivacaine concentration ratio (λ) varies with packed cell volume (PCV).[22] However, because of the perioperative transfusion policy, postoperative PCV of our patients did not vary widely (0.33–0.44). λ may be related to PCV by the equation $\lambda = -0.0079\ \mathrm{PCV} + 1.028$,[22] so that calculated total blood bupivacaine concentrations varied from 23 to 31% higher than our reported serum concentrations. Thus the variation in PCV in our patients resulted in a maximum inaccuracy in calculated total bupivacaine concentrations of approximately 8%. However, by using the same analytical technique as in our first study, we have been able to compare directly our present results with previous data.

We had hypothesized that the provision of adequate postoperative analgesia, without recourse to opioid medication, would enable earlier tracheal extubation than would otherwise have been the case. Eight of the patients we studied required controlled ventilation before operation and, subsequently, for 26.3 (9.4) h after operation. Retrospective data obtained from five consecutive infants having repair of coarctation who required artificial ventilation both before and after operation, but who received morphine for analgesia, showed a mean time to extubation of 46.5 (4.5) h. Although such small numbers make any definitive conclusions unwarranted, we suggest that the duration of postoperative ventilation in infants without other medical or surgical problems may be reduced by using non-opioid rather than opioid analgesia. Seven other patients in our study required postoperative intubation for 3–48 h because of surgical complications, medical problems or excessive tracheal secretions not conducive to early extubation. Despite these babies' tracheas being intubated, our nurses were able to assess facial grimacing, movement and physiological changes, such that pain scores could be assessed.

In our study we found that the technique of continuous extrapleural paravertebral infusion of bupivacaine provided effective analgesia in 86% (18 of 21) of our patients. Our "success" rate is slightly lower than that described in previous studies in infants[1] and children,[25] which used higher doses of bupivacaine. This comparison could be interpreted to indicate that, at least in some of our patients, the dose of bupivacaine administered was too low. If this had not been a research investigation, we would have tried to increase efficacy by increasing the infusion rate, but we did not attempt this strategy in our three "failure" patients, as their serum bupivacaine concentration data would not be comparable. A temporary increase in infusion rate would appear safe within the first 24 h after operation, although after 30 h such a strategy may lead to an increased risk of toxicity. The regular addition of paracetamol would also seem a sensible adjunct to this technique. Hopefully, in the near future, this useful analgesic technique may be made even safer by the use of ropivacaine rather than bupivacaine.[26]

Gut mucosal perfusion in infants undergoing cardiopulmonary bypass: effect of preoperative captopril

P. D. BOOKER, A. J. M. DAVIS AND R. FRANKS

Summary

We have studied gut mucosal perfusion in 24 infants, aged 0.7–45 weeks, requiring cardiopulmonary bypass (CPB). Group 2 patients (n=12) had received the angiotensin converting enzyme inhibitor captopril 0.8–0.9 mg kg^{-1} orally, 45 min before induction of anaesthesia. Group 1 infants were of similar age and size and required a similar duration of CPB, but did not receive any preoperative medication. An orogastric tonometer allowed intermittent calculations of gastric intramucosal pH (pH$_i$), and rectal mucosal perfusion ("flux") was monitored using laser Doppler flowmetry. Measurements of arterial base deficit and lactate and pyruvate concentrations were made intermittently. We found no significant difference in femoral arterial pressure between the groups at any time before, during or after surgery. Similarly, we found no significant differences in our measures of regional or global tissue perfusion between the groups at any time before, during or after surgery. We conclude that preoperative administration of captopril produced no beneficial effect on gut mucosal perfusion in infants undergoing hypothermic, non-pulsatile CPB. (*Br. J. Anaesth.* 1997; **79**: 14–18).

Key words
Measurement techniques, flowmetry. Measurement techniques, tonometry. Gastrointestinal tract, mucosal perfusion. Heart, cardiopulmonary bypass. Pharmacology, captopril. Surgery, cardiovascular.

We have shown previously that infants undergoing hypothermic, non-pulsatile cardiopulmonary bypass (CPB) may demonstrate significant decreases in gut mucosal perfusion, as measured by gastric tonometry and laser Doppler flowmetry.[1] Similar significant decreases in gastric pH$_i$ have also been shown in adults during and after cardiac surgery.[2 3] Severe reductions in mucosal perfusion may be a causative factor in postoperative necrotizing enterocolitis[4] or multiple organ dysfunction.[5]

Although it is probable that multiple control mechanisms exist in the intestinal microcirculation with different mediators affecting vessels of different sizes, the renin–angiotensin system may play a pivotal role in the generation of gut hypoperfusion during CPB. Animal studies have suggested that splanchnic vessels are particularly sensitive to the vasoconstrictive effects of angiotensin II.[6 7] However, the large increase in angiotensin II concentrations induced by CPB demonstrated in adults by some workers[8] has not been a constant finding.[9 10] The reason for these different results is not known, although varying degrees of hypotension,[11] pulmonary blood flow,[12] angiotensin converting enzyme (ACE) concentrations[13] and hypothermia[9] may be relevant. No similar work has been performed in infants or children, although it has been shown that baseline renin–angiotensin activity tends to be higher in early infancy than in later childhood.[14]

Both in an animal model[15] and in healthy volunteers,[16] it has been shown that ACE inhibition causes significant splanchnic vasodilatation. ACE inhibition has been shown in an animal model to prevent splanchnic vasoconstriction and protect the gut from ischaemic injury after haemorrhage[17] and cardiogenic shock.[18] Furthermore, ACE inhibitors given in the peroperative period to adults undergoing heart surgery appear to suppress the increases in atrial natriuretic peptide, endothelin-1 and noradrenaline concentrations that would otherwise occur during and after CPB.[19]

In a prospective, controlled study, we have compared gut mucosal perfusion during CPB in infants receiving ACE inhibitors for medical reasons, with a similarly aged control group. We used a tonometric technique to assess gastric mucosal perfusion and laser Doppler flowmetry to monitor rectal mucosal perfusion.

Patients and methods

With local Ethics Committee approval and written, informed parental consent, we studied 24 infants >2.0 kg in weight, aged 0.7–45 weeks, requiring elective CPB. Twelve infants had been receiving captopril 0.8–0.9 mg kg^{-1} orally, four times a day, for at least 4 weeks before operation. Patients with coarctation and those who required vasoactive drugs other than ACE inhibitors before operation were excluded.

Patients in the captopril group (group 2) received their normal dose of captopril 45 min before induction of anaesthesia, on average 148 (18) min before initiation of CPB (see table 1). No premedication was given to any patient. Anaesthesia was induced with thiopentone 4 mg kg^{-1} and neuromuscular block produced with vecuronium 0.2 mg kg^{-1} h^{-1}. Anaesthesia was maintained with i.v. infusions of midazolam 240 μg kg^{-1} h^{-1} and diamorphine 24 μg kg^{-1} h^{-1}, supplemented with 0.25–0.5% isoflurane in oxygen or air, or both, before CPB. A central venous catheter was inserted and a femoral artery cannulated for monitoring systemic arterial pressure. A urinary catheter and nasopharyngeal and oesophageal temperature probes were inserted and a peripheral tissue oxygen saturation probe was taped in place.

After routine probe calibration, a laser Doppler probe (Moor Instruments Ltd) was inserted 7–8 cm into the patient's rectum, the probe's special design ensuring that its optical prism lay against the mucosa.[20] The probe was connected to a MBF3 monitor (Moor Instruments Ltd) and computer; later analysis of recordings was made using Moorsoft data interpretation software (Moor Instruments Ltd). A TRIP sigmoid tonometer (Tonometrics, Inc., MA, USA) was inserted orally into the patients stomach and connected to a Tonocap monitor (Datex UK, Ltd), which intermittently analysed $P\text{CO}_2$ in the tonometer balloon ($P\text{r}_{\text{CO}_2}$). Subsequent calculation of pH_i was made using the formula:

$$\text{pH}_\text{i}=\text{pH}+\log^{10}(P\text{a}_{\text{CO}_2}/P\text{r}_{\text{CO}_2})$$

Arterial pH and $P\text{a}_{\text{CO}_2}$ were obtained by simultaneous measurement of arterial blood-gas tensions. Correct positioning of the tonometer was aided by the sight of a small bulging of the anterior abdominal wall as it was gently advanced, later confirmed by chest x-ray taken after operation.

After sternotomy, but before manipulation of the great vessels, baseline recordings of rectal mucosal flux and femoral mean arterial pressure (MAP) were made over a 5-min period. A sample of arterial blood was obtained for measurement of pH, $P\text{a}_{\text{O}_2}$, $P\text{a}_{\text{CO}_2}$, ionic calcium (Ca^{2+}), haematocrit (PCV) and base deficit, at the same time as a gastric tonometer $P\text{r}_{\text{CO}_2}$ measurement was made. In addition, a blood sample was obtained to allow measurement of lactate and pyruvate concentrations and, subsequently, the lactate/pyruvate (L/P) ratio was calculated.

The hollow fibre D701 oxygenator (Dideco) used for CPB was primed with warmed blood and crystalloid such that blood and core temperatures 10 min after initiation of CPB were 34±0.5 °C and PCV 25±5%. When the patient had been established on non-pulsatile CPB at a flow rate of 100 ml kg^{-1} min^{-1} for 10 min and nasopharyngeal temperature remained constant to within ±0.1 °C, another arterial blood sample was obtained for measurement of PCV, base deficit, and lactate and pyruvate concentrations. MAP and rectal mucosal flux were recorded for another 5 min before the patient was cooled to 15–25 °C, depending on the anticipated duration of low flow or circulatory arrest required. The rate of cooling and rewarming was controlled to approximately 1 °C min^{-1}. Throughout CPB, PCV was maintained at 25±5% and Ca^{2+} concentration and base deficit were kept within normal limits, although no drug was given within 15 min of any observation period. Intermittent arterial blood-gas measurements were used to maintain a constant $P\text{a}_{\text{O}_2}$ (20±5 kPa) throughout CPB, aided by the use of an in-line $P\text{a}_{\text{O}_2}$ monitor (Polystan). Similarly, the Tonocap capnograph (Datex Ltd), attached to the gas outlet port of the oxygenator, helped to maintain a constant $P\text{a}_{\text{CO}_2}$ (5.3±0.5 kPa, temperature uncorrected, i.e. alpha-stat regulation). When the patient was rewarmed on CPB to 35 °C, and core temperatures remained stable to within ±0.1 °C over 5 min, another set of blood samples, flux, $P\text{r}_{\text{CO}_2}$ and haemodynamic readings were obtained.

When these rewarm readings were completed, all patients were given enoximone 1.0 mg kg^{-1} followed by infusion of 10 μg kg^{-1} min^{-1} to aid weaning from CPB. Patients undergoing an arterial switch operation also required dobutamine 10 μg kg^{-1} min^{-1} to maintain MAP >40 mm Hg after CPB. When haemodynamic variables were stable, another set of blood samples, flux, $P\text{r}_{\text{CO}_2}$ and haemodynamic readings were obtained approximately 20 and 60 min after weaning from CPB.

Before the study started we had calculated that if we studied 11 patients in each group, we should be able to detect a difference of 70 in mean flux between the groups as being significant ($P<0.05$) with a power of 90%, assuming an SD of 50. Study data have not invalidated this assumption. Comparisons between mean flux, mean pH_i, mean MAP, mean base deficit and mean L/P ratio obtained at each time (before CPB, at initial warm CPB after injection, on CPB after rewarming and after CPB) in the two groups were analysed using the Wilcoxon test and SPSS exact test. Kendall's tau-*b* rank correlation coefficient was used to assess associations between MAP, base deficit, flux, pH_i and L/P ratios at each study period.

Results

Infants in control group 1 were slightly younger and smaller than those in group 2 (tables 1, 2). Cardiopulmonary bypass (CPB) and aortic clamp times were slightly longer in group 1 than in group 2 patients, although this difference was not statistically significant. We were unable to demonstrate any significant difference between the two groups at any time, in either measure of global tissue perfusion (L/P ratio and base deficit), or regional tissue perfusion indicators (gastric pH_i and rectal mucosal flux) (tables 3–5). Similarly, there was no evidence that preoperative captopril had any effect on MAP before, during or after surgery.

There were significant correlations between arterial base deficit and pH_i at all times before and after CPB. There was also a significant correlation between our other global index of tissue hypoxia, L/P ratio, and gastric pH_i at 60 min after CPB. Anomalous correlations between L/P ratio and flux after rewarming, and between MAP and pH_i at 20

Discussion

We were unable to demonstrate that inhibition of ACE, using captopril given before operation, increased gut mucosal perfusion in infants undergoing non-pulsatile, hypothermic CPB, compared with a matched control group. This lack of effect may have been caused by inadequate ACE inhibition, other vasoconstrictor activity may have been more influential or our methods of assessing splanchnic perfusion may have been too insensitive. However, a more likely reason for the non-significant difference between the groups may have been that gut perfusion demonstrated in the control group before, during and after CPB was normal. We have

shown previously that neonates with coarctation or other aortic arch anomalies are at particular risk of gut mucosal hypoxia.[1] Although this group of patients would probably benefit most from therapy aimed at improving gut mucosal blood flow during CPB, such patients are unlikely to receive an ACE inhibitor before operation.

We made the assumption that oral administration of captopril 45 min before induction of anaesthesia would allow time for normal absorption to occur. Studies of captopril kinetics in children[21 22] suggest that the peak effect normally occurs 1.0–1.5 h after ingestion. As the duration of action of captopril is 6–10 h in children,[22] and longer in neonates, [23] it should have been exerting an inhibitory effect on angiotensin II production throughout CPB in all group 2 patients (see tables 1, 2). Nevertheless, as we did not measure angiotensin II concentrations in these patients we cannot be sure that this assumption is valid.

Arterial pressure is volume-dependent during ACE inhibition and one poorly controlled adult study suggested that after CPB vasoconstrictor requirements may be increased in patients receiving ACE inhibitors before operation.[24] However, other clinical studies in adults have been unable to demonstrate any difference between treated and untreated patients in perioperative arterial pressure or fluid requirements.[25 26] Similarly, we found no significant difference between our two groups of patients in either perioperative MAP or inotrope requirements after CPB.

Measurement of saline $P\text{CO}_2$ may be an important source of error in the assessment of gastric intramucosal pH, the error depending on the solution[27] and analyser being used.[28] Furthermore, in patients with a high tonometric $P\text{r}_{\text{CO}_2}$, saline tonometry has a tendency to underestimate the degree of tissue hypercapnia.[28 29] The Tonocap (Datex, Ltd) uses a method of measuring tissue carbon dioxide that avoids these potential inaccuracies. The Tonocap fills the TRIP (Tonometrics, Inc.) catheter balloon with air which is retained for a period of at least 15 min, to allow carbon dioxide diffusion and gas equilibration to take place. The Tonocap then withdraws a gas sample from the balloon automatically and measures $P\text{CO}_2$ using an infrared measurement technique. The Tonocap then re-injects the gas into the balloon, so that carbon dioxide depletion is reduced and faster and more complete gas equilibration is possible before the next sample is obtained. Initial studies have shown a significant correlation between results obtained using air tonometry and those obtained using conventional saline tonometry.[29 30] In accordance with the manufacturer's recommendations, we checked the accuracy of the monitor with calibration gas at least every 2 weeks or before every patient, whichever was the shorter interval. For properly calibrated monitors, the accuracy in carbon dioxide measurement, as stated by the manufacturer, is ±0.2 kPa.

To use a laser Doppler flowmetry technique to monitor mucosal blood flow it has to be assumed that a tissue measurement volume of approximately 6 mm^3 is representative of the region under examination and that there is vascular homogeneity within the tissue. Furthermore, to ensure consistency of observations from patient to patient, regular probe calibrations are necessary. We have not found that flux readings are unduly position-sensitive provided the probe is positioned such that the flux reading is the maximum that can be obtained and that a pulsatile waveform is seen. Tissue movement affects readings and this technique can only generate reproducible results in paralysed patients.

In a previous study[1] which compared infants with aortic arch obstruction with a group with normal arch anatomy, we did not find the consistent correlations between base deficit and pH_i that we found in this study. Perhaps this may be explained by the fact that patients in this study had relatively normal gut perfusion, and changes in regional perfusion reflected only changes in whole body perfusion. In our previous study, it could be assumed that the more abnormal gut perfusion seen in the study group did not reflect whole body perfusion in a consistent manner. Nevertheless, if this were the entire explanation, we should have seen similar correlations between L/P ratios and pH_i, which did not occur.

There are good reasons to suppose that gut mucosal perfusion may be enhanced after administration of captopril, as ACE inhibition not only suppresses angiotensin production but endothelin and catecholamine production are also inhibited.[19] Furthermore, ACE is identical to kininase, an enzyme that cleaves bradykinin, and increased plasma concentrations of bradykinin, a potent vasodilator, result from ACE inhibition. ACE inhibitors also increase prostaglandin E_2 synthesis,[31] decrease noradrenaline release from adrenergic nerves and adrenal medulla, and decrease vascular responsiveness to noradrenaline.[32] Nevertheless, our study has been unable to demonstrate that captopril offers any benefit, in terms of gut perfusion, to infants requiring elective CPB. However, it is possible that ACE inhibition may improve gut mucosal perfusion only in those infants who have prolonged and severe gut mucosal hypoxia, such as those with coarctation or interrupted aortic arch.

Interactions between mivacurium and pancuronium

K. S. KIM, J. C. SHIM AND D. W. KIM

Summary

We have compared the dose–response relationships of mivacurium, pancuronium and their combination, and examined the interactions by isobolographic and fractional analyses. We studied 70 adult patients during nitrous oxide–fentanyl–propofol anaesthesia. The dose–response curves were determined by probit analysis. The ED_{95} and ED_{50} values for mivacurium were 84.2 (95% confidence interval 80.2–88.1) μg kg^{-1} and 46.2 (40.2–52.1) μg kg^{-1}, respectively. Corresponding values for pancuronium were 68.5 (63.7–73.2) μg kg^{-1} and 40.7 (35.5–45.9) μg kg^{-1}, respectively. Isobolographic and fractional analyses of the mivacurium–pancuronium combination demonstrated a synergistic interaction. An additional 30 patients were allocated randomly to receive either mivacurium 84.2 μg kg^{-1} (n=15) or pancuronium 68.5 μg kg^{-1} (n=15). When the first twitch (T1) of TOF recovered to 25%, each patient received mivacurium 46.2 μg kg^{-1}. The times after administration of mivacurium until T1 25% in the mivacurium–pancuronium group were 6.4 (3.5–9.4) min and 49.8 (44.7–54.9) min, respectively (P<0.0001). We conclude that the combination of mivacurium and pancuronium was synergistic and after pancuronium-induced neuromuscular block, mivacurium became a longer acting agent than the shorter agent. (*Br. J. Anaesth.* 1997; **79**: 19–23).

Key words
Neuromuscular block, mivacurium. Neuromuscular block, pancuronium. Neuromuscular block, measurement of response. Potency, anaesthetic, ED_{50}.

Mivacurium chloride is a short-acting, non-depolarizing neuromuscular blocking agent of the benzylisoquinoline type.[1 2] Pancuronium bromide is a long-acting, steroidal neuromuscular blocking agent and is often used when the estimated time of surgery is long.[3]

Mivacurium may be a more useful agent at the end of surgery compared with pancuronium if it retains its short-acting nature when given in combination with pancuronium. By doing this, it may be possible to maintain good clinical neuromuscular block but enable reversal in a few minutes to a safe level of recovery.

This study was undertaken to characterize the interaction of a combination of mivacurium and pancuronium in humans using the isobolographic method and to study the effects of non-depolarizing block when mivacurium was administered during recovery from pancuronium-induced neuromuscular block.

Patients and methods

After obtaining Hospital Ethics Committee approval and informed consent, we studied ASA I or II patients, aged 19–57 yr, undergoing elective surgical procedures. No patient had any disease or metabolic abnormality known to alter neuromuscular transmission, or was receiving any drug known or suspected of interfering with neuromuscular function. ECG, pulse oximetry and non-invasive arterial pressure were monitored. Palm skin temperature of the hand, where neuromuscular function was monitored, was maintained at >33 °C.

INTERACTION STUDIES

Anaesthesia was induced with fentanyl 4–5 μg kg^{-1}, propofol 2–2.5 mg kg^{-1} and 70% nitrous oxide in oxygen, and maintained with a continuous infusion of propofol 8–10 mg kg^{-1} h^{-1} and 70% nitrous oxide in oxygen supplemented with intermittent bolus doses of fentanyl 1–2 μg kg^{-1}. Ventilation was adjusted to maintain normocapnia (end-tidal carbon dioxide partial pressure 4.9–5.5 kPa).

The ulnar nerve was stimulated at the wrist with square-wave supramaximal stimuli of 0.2 ms duration, delivered in a train-of-four (TOF) sequence at 2 Hz every 10 s, using a Myotest DBS peripheral nerve stimulator (Biometer Co., Odense, Denmark). The resultant contraction of the adductor pollicis was recorded using a force displacement transducer and neuromuscular function analyser (Myograph 2000, Biometer Co., Odense, Denmark). Preload tension of the thumb was maintained at 300 g throughout the investigation. The first twitch (T1) of the TOF was considered twitch height.

After stable recording of neuromuscular transmission had been established for a minimum of 30 min, we created dose–response curves for mivacurium, pancuronium and the combination of mivacurium

and pancuronium. For mivacurium, we used a single-dose method because mivacurium is short-acting.[4] A subgroup of 30 patients was allocated randomly to receive mivacurium 30, 45 or 60 $\mu g\ kg^{-1}$ (10 patients for each dose). After administration of mivacurium, maximal twitch depression was assessed and anaesthesia was continued thereafter. The percentage values for twitch depression in each dose were transformed to probits and plotted against the logarithm of the dose. Subsequently, dose–response curves were obtained by least square linear regression analysis of the log-dose and probit-response values.[5]

Another subgroup of 20 patients received pancuronium in incremental doses to establish cumulative dose–response curves for pancuronium.[6] Patients received pancuronium 30 $\mu g\ kg^{-1}$ as their first dose of neuromuscular blocker. Incremental doses (15 $\mu g\ kg^{-1}$) were administered when twitch height remained constant for three consecutive twitches. After approximately 95% depression after the last incremental dose, anaesthesia was continued as required. The percentage values for twitch depression were transformed to probit means. The cumulative dose–response curve was determined by log–probit transformation of the data. From the dose–response curves of mivacurium and pancuronium administered alone, the respective ED_{95} and ED_{50} (effective dose resulting in 95% and 50% reduction in T1) values were determined.

The following predetermined doses of drugs were administered to another subgroup (20 patients): mivacurium and pancuronium, respectively, 13.9 and 12.2 $\mu g\ kg^{-1}$, 18.5 and 16.3 $\mu g\ kg^{-1}$, and 23.1 and 20.4 $\mu g\ kg^{-1}$. Studies of the single-drug groups were concluded first, so that doses of the combination could be planned. From the dose–response curves of the neuromuscular agents administered alone, we determined the respective ED_{50}. Subsequently, dose–response curves were obtained by administration of the drug combinations in a constant dose ratio based on the ED_{50} values of the single agent.

For the mivacurium–pancuronium combination, the following combinations after a pilot study were administered: 0.3 ED_{50} mivacurium +0.3 ED_{50} pancuronium; 0.4 ED_{50} mivacurium +0.4 ED_{50} pancuronium; and 0.5 ED_{50} mivacurium +0.5 ED_{50} pancuronium. Regression lines were compared using analysis of covariance.

All drugs were injected over 5 s into a rapidly flowing i.v. infusion. In the combination group, drugs were injected simultaneously into two separate i.v. cannulae inserted in one arm.

Isobolographic analysis[7 8] was used to define the type of interaction between mivacurium and pancuronium. This analysis has the advantage of being independent of the slopes of the dose–response curves, that is parallelism does not have to be established. It was used to confirm the interactions between neuromuscular blocking agents.[9–12] If the ED_{50} of a combination falls on the theoretical additive line, the effect of the drug mixture is additive. Points to the left of the theoretical additive line would be consistent with a synergistic interaction, whereas points to the right of the line would indicate an antagonistic interaction. Confidence intervals for each points were calculated from the variances of each component alone and were evaluated for statistical significance using the unpaired Student's *t* test.

Fractional analysis[13] was based on the expression of the component doses of the two agents for the combination as fractions of the doses that produce the same effect when given separately. Values near 1 indicate additive interaction, values greater than 1 imply antagonism and values less than 1 indicate synergism. This analysis was also used to confirm the interaction between neuromuscular blocking agents.[10–12]

CLINICAL STUDIES

Selection of patients, anaesthesia and preparation for the study were similar to those described in the interaction studies. After stable recording of neuromuscular transmission for a minimum of 30 min, 30 patients were allocated randomly to receive mivacurium followed by mivacurium, or pancuronium followed by mivacurium. An ED_{95} dose of mivacurium (84.2 $\mu g\ kg^{-1}$) or pancuronium (68.5 $\mu g\ kg^{-1}$) from the interaction studies was administered. If 90% neuromuscular block was not achieved, an additional dose (20 $\mu g\ kg^{-1}$) of mivacurium or pancuronium was given. Tracheal intubation was performed when neuromuscular block exceeded 95%. When the T1 response recovered to 25% after mivacurium or pancuronium, each patient received a dose of mivacurium equivalent to the ED_{50} (46.2 $\mu g\ kg^{-1}$), determined from the interaction studies. Thereafter, full spontaneous recovery of neuromuscular function was recorded in every patient. The criteria for full recovery were steady-state recovery of T1 response and a TOF ratio >0.7. Thereafter, anaesthesia was continued as indicated by individual patient care.

After mivacurium 46.2 $\mu g\ kg^{-1}$, the time from administration to maximal block was measured, and times to 1%, 25%, 75% and 95% recovery of T1 response, and the recovery index (T1 recovery from 25% to 75%) were recorded. The time from administration of mivacurium 46.2 $\mu g\ kg^{-1}$ to recovery of a TOF ratio of 0.7 was analysed.

For statistical analysis, linear regression analysis, analysis of covariance, unpaired Student's *t* test and analysis of variance were used. Unless otherwise specified, the results are expressed as mean (95% confidence intervals) and were considered significant when $P<0.05$.

Results

INTERACTION STUDIES

Patient characteristics did not differ between groups (table 1). Calculated doses for ED_{50} values for twitch depression were 46.2 (95% confidence interval 40.2–52.1) $\mu g\ kg^{-1}$ and 40.7 (35.5–45.9) $\mu g\ kg^{-1}$ for mivacurium and pancuronium, respectively. Corresponding ED_{95} values were 84.2 (80.2–88.1) $\mu g\ kg^{-1}$ and 68.5 (63.7–73.2) $\mu g\ kg^{-1}$, respectively.

Pancuronium	—	—	1	40.7 (35.5–45.9)	1
Combination	0.19	8.8 (5.7–11.9)	0.19	7.7 (5.9–9.5)	0.38

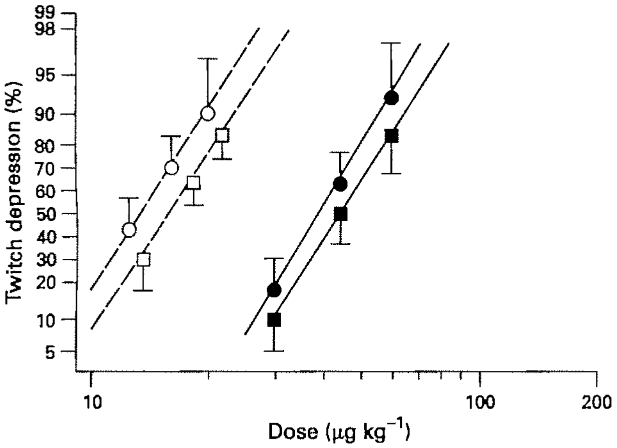

Figure 1 Log dose–probit plot for twitch depression for mivacurium with (☐) or without (■) pancuronium, and pancuronium with (○) or without (●) mivacurium. Individual points represent mean (95% confidence intervals) twitch depression (% control) with each dose.

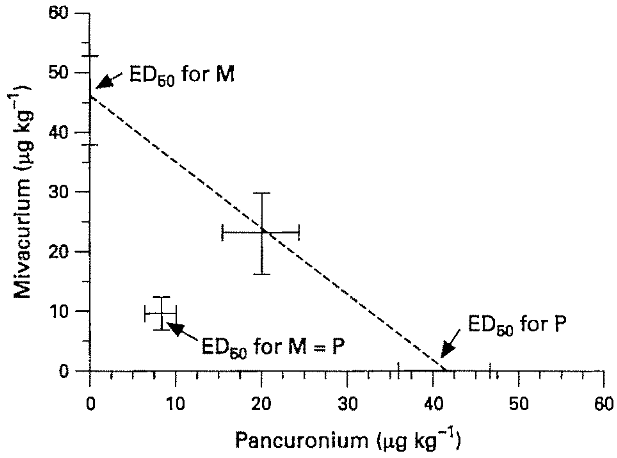

Figure 2 First twitch ED_{50} isobologram for the interaction of mivacurium (M) and pancuronium (P). The broken line connecting the single drug ED_{50} points is the theoretical additive line; the point on this line is the theoretical additive points (95% confidence intervals). The experimentally determined ED_{50} dose (95% confidence intervals) of the mivacurium–pancuronium (M=P) combination showed significantly synergistic effects ($P<0.0001$).

The dose–response curves are shown in figure 1. The slopes for mivacurium alone, pancuronium alone, mivacurium combined with pancuronium and pancuronium combined with mivacurium were, respectively, 3.1 (2.8–3.4), 3.4 (2.9–3.9), 2.8 (2.5–3.2) and 3.0 (2.6–3.4). The slopes were not significantly different. Isobolographic analysis demonstrated synergistic interactions with respect to the neuromuscular blocking activity of the mivacurium–pancuronium combination (fig. 2).

The experimentally determined ED_{50} value for the combination was 8.8 (5.7–11.9) $\mu g\ kg^{-1}$ for mivacurium and 7.7 (5.9–9.5) $\mu g\ kg^{-1}$ for pancuronium. The theoretical additive ED_{50} value was calculated as 23.1 (17.2–29.1) $\mu g\ kg^{-1}$ for mivacurium and 20.4 (16.9–23.9) $\mu g\ kg^{-1}$ for pancuronium. The confidence intervals of these points did not overlap and the result of Student's *t* test for potency ratio was significant ($P<0.0001$). Fractional analysis of this interaction also demonstrated synergism (table 2).

CLINICAL STUDIES

After mivacurium 88.1 (81.3–94.9) $\mu g\ kg^{-1}$, there was 97 (94–99) % neuromuscular block. After pancuronium 70.8 (64.5–77.1) $\mu g\ kg^{-1}$, there was 96 (93–99) % neuromuscular block. The time course of mivacurium-induced neuromuscular block in the different groups are presented in figure 3. Onset times to maximum block after mivacurium 46.2 $\mu g\ kg^{-1}$ did not differ between the mivacurium (138.2 (109.3–167.1) s) and pancuronium (101.4 (79.2–123.6) s) groups, but there was a rapid onset time in the pancuronium group. The times after mivacurium 46.2 $\mu g\ kg^{-1}$ until T1 25% recovery (clinical duration) in the mivacurium and pancuronium groups were 6.4 (3.5–9.4) min and 49.8 (44.7–54.9) min, respectively ($P<0.0001$). Corresponding times until T1 95% recovery were 12.7 (10–15.4) min and 90.2 (83.1–97.3) min, respectively ($P<0.0001$). Corresponding recovery indexes were 4.7 (3.9–5.5) min and 21.8 (18.7–24.9) min, respectively ($P<0.0001$). Corresponding times until a TOF ratio of 0.7 were 14.2 (11.1–17.3) min and 103.4 (94.3–112.5) min, respectively ($P<0.0001$).

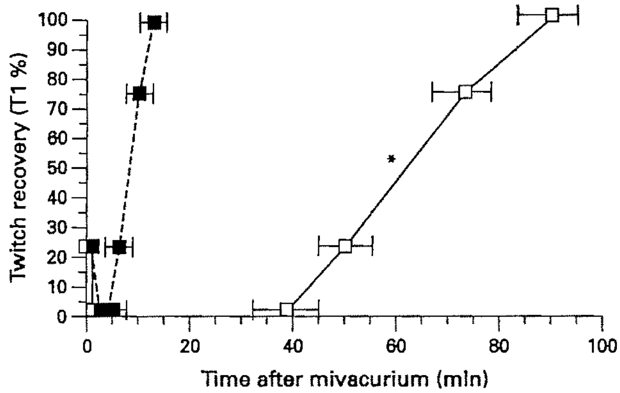

Figure 3 Spontaneous first twitch (T1) recovery of train-of-four after mivacurium 46.2 μg kg^{-1} given at T1 25% during recovery from mivacurium (■) or pancuronium (□) block. Groups differed from each other with the exception of onset time (*$P<0.0001$) Individual points represent mean (95% confidence intervals) time after mivacurium.

Discussion

Using isobolographic analysis, we have demonstrated that the combination of mivacurium and pancuronium exerted greater synergistic effect than that seen with either agent administered alone. Fractional analysis of this interaction also demonstrated a synergistic interaction, that is the effect of the combination was precisely that expected from the dose–response relationships of the individual agents. The clinical duration of action of mivacurium 46.2 μg kg^{-1} given after mivacurium was 6.4 min, while after pancuronium this mivacurium dose prolonged the clinical duration eight-fold to 49.8 min.

In this study, the calculated first twitch ED$_{50}$ and ED$_{95}$ values for mivacurium during nitrous oxide–fentanyl–propofol anaesthesia were 46.2 (40.2–52.1) μg kg^{-1} and 84.2 (80.2–88.1) μg kg^{-1}, respectively. Similar values (52 and 81 μg kg^{-1}, respectively) were reported by Savarese and colleagues[2] and by Rautoma, Erkola and Meretoja[14] (57.7 and 104.4 μg kg^{-1}, respectively) for nitrous oxide–opioid and thiopentone or propofol anaesthesia. The ED$_{50}$ and ED$_{95}$ values of 40.7 (35.5–45.9) and 68.5 (63.7–73.2) μg kg^{-1}, respectively, for pancuronium calculated in this study were in close agreement (35.7 (31.9–39.8) and 64.4 (57.5–71.8) μg kg^{-1}, respectively) with those reported by Gramstad and Lilleaasen,[15] Foldes and colleagues[16] (33 and 49 μg kg^{-1}, respectively) and Rautoma, Erkola and Meretoja[14] (37.1 and 64.8 μg kg^{-1}, respectively) during nitrous oxide–opioid and thiopentone or propofol anaesthesia. The dose–response curve for pancuronium was not significantly steeper than that for mivacurium, which is in agreement with a previous report.[14]

Synergism between mivacurium and pancuronium may exist in children[17] and adults,[14,18] but we could not find any isobolographic or fractional analyses of the mivacurium–pancuronium combination. The structural similarity or dissimilarity between the interacting neuromuscular blocking agents may have an effect.[19] Combinations of structurally similar neuromuscular blocking drugs (pipecuronium and vecuronium, rocuronium and other aminosteroids, atracurium and mivacurium) produce an additive response in isobolographic analyses.[9–11] Structurally different blockers may potentiate each other more than structurally similar blockers.[14,19,20]

Rautoma, Erkola and Meretoja[14] reported that the combined use of mivacurium and pancuronium could reduce their requirements by approximately 40%. In this study, the sum of fractions for the mivacurium–pancuronium combination was 0.38 compared with the ED$_{50}$ value of mivacurium or pancuronium (table 2). This combination could reduce requirements by 62%. The methodological difference between the study of Rautoma, Erkola and Meretoja and the present investigation is only a combination of 0.5 times the ED$_{50}$ of mivacurium and pancuronium. But we obtained the ED$_{50}$ for the combination of drugs from the dose–response curves (fig. 1) analysed by isobolographic and fractional analyses (fig. 2, table 2). In another study where atracurium and vecuronium were used together, the maximal reduction in drug consumption was approximately 30%.[21]

Synergism between mivacurium and pancuronium (which have dissimilar molecular structures) may be related to their differential actions on pre- and postsynaptic acetylcholine receptors,[19] differential sensitivity of the α-subunit acetylcholine recognition sites[22] and effects on plasma cholinesterase.[23]

In a study in which mivacurium 70 μg kg^{-1} was given at T1 25% during recovery from pancuronium block, the clinical duration was prolonged from 10 to 54 min compared with that after mivacurium block alone.[18] In this study, we also obtained similar changes in clinical duration (from 6.4 (3.5–9.4) min to 49.8 (44.7–54.9) min) for a mivacurium dose of 46.2 μg kg^{-1}. It has been suggested that the long elimination half-life of the underlying longer acting blocker prolongs the effects of the subsequent shorter acting drug.[24]

The clinical duration of action after pancuronium 80 μg kg^{-1} was 44 (SD 10) min during nitrous oxide–opioid–thiopentone anaesthesia.[25] In this study, a similar clinical duration (49.8 (44.7–54.9) min) was obtained after mivacurium in the pancuronium group. It was suggested that after pacuronium-induced neuromuscular block, mivacurium became a longer acting agent than the shorter agent, but shorter than the longer agent. Middleton and colleagues[26] suggested that the majority of receptors remain occupied by the drug administered initially; clinical duration depends more on the kinetics of the first neuromuscular blocking drug than the subsequently administered drug.

Pancuronium is known to inhibit plasma cholinesterase which degrades mivacurium.[2,23,27] Plasma cholinesterase activity has been shown to decrease by 15% or less after pancuronium 20 μg kg^{-1}.[23] On the other hand, clinically useful doses of pancuronium have been noted to inhibit plasma cholinesterase *in vitro* to a clinically insignificant amount.[28] A small dose of pancuronium might have only minimal effects on plasma cholinesterase.[14] Therefore, we did not investigate effects on plasma cholinesterase.

We conclude that the interaction of mivacurium and pancuronium was the result of synergistic actions at the neuromuscular junction, and after pancuronium-induced neuromuscular block, mivacurium became a longer acting agent than the shorter agent.

Blood flow and mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles

M. ABDULATIF AND M. EL-SANABARY

Summary

We have studied the pattern of blood flow and pharmacodynamic profile of mivacurium-induced block at the adductor pollicis and orbicularis oculi muscles. We studied 30 adult patients anaesthetized with fentanyl, thiopentone, nitrous oxide–isoflurane, and mivacurium 0.2 mg kg^{-1}. Neuromuscular transmission was monitored with accelerometry (TOF Guard, Biometer, Denmark). Blood flow was measured at the two muscles with the use of a laser Doppler flowmeter (Laserflo BPM^2, Vasamedics, USA). All patients developed 100% neuromuscular block at the adductor pollicis muscle. Mean maximum neuromuscular block at the orbicularis oculi was 96.4 (SD 3.5) % (ns). Onset time, time required for 25% and 75% recovery of the first twitch in the train-of-four (T1), and a train-of-four ratio (T4/T1) of 90% at the orbicularis oculi were respectively, mean 130.4 (SD 28.5) s, 9.1 (3.2) min, 16.2 (3.9) min and 20.2 (4.3) min and were significantly shorter than the corresponding values at the adductor pollicis: 202.7 (37.2) s, 12.9 (3.9) min, 21.1 (5.1) min and 30.8 (7.4) min. For a given T1, there was significantly less train-of-four fade (T4/T1) at the orbicularis oculi than at the adductor pollicis muscle during recovery. Blood flow was comparable at the two muscles before induction of anaesthesia. Thiopentone significantly increased thenar muscle blood flow from 2.9 (1.5) to 12.3 (6.8) ml 100 g^{-1} min^{-1}, with a further increase to 22.7 (8.0) ml 100 g^{-1} min^{-1} after isoflurane ($P<0.001$). Blood flow at the orbicularis oculi was not altered by thiopentone or isoflurane and was consistently lower than that at the adductor pollicis muscle. We conclude that the different pharmacodynamic profiles of mivacurium-induced block at the orbicularis oculi and adductor pollicis muscles were not related primarily to a difference in blood flows. (*Br. J. Anaesth.* 1997; **79**: 24–28).

Key words
Neuromuscular block, mivacurium. Neuromuscular block, measurement of response. Blood, flow. Muscle skeletal. Muscle skeletal, blood flow. Measurement techniques, flowmetry.

The response to a bolus dose of a neuromuscular blocking drug depends on which muscle is examined.[1] There can be differences in both onset time and sensitivity between various muscles. For example, the orbicularis oculi tends to require a larger dose for the same degree of paralysis compared with the adductor pollicis muscle. However, onset of paralysis is faster at the former.[2–4] These two apparently contradictory effects depend on different factors. The dose required for a given effect in a specific muscle depends largely on the concentration required to block the receptors.[1] On the other hand, onset time is determined to a great extent on the rate at which the drug gains access to the receptors.[1] In dogs, the onset time of gallamine-induced neuromuscular block in the tibialis anterior muscle was found to be shortened by increasing blood flow to the muscle.[5]

Human studies correlating neuromuscular response at different muscles with blood flow are lacking. With the recent availability of laser Doppler flowmeters, continuous monitoring of microcirculatory blood flow has become possible.[6 7] Using this technique we have compared blood flow at the orbicularis oculi and adductor pollicis muscles in patients during fentanyl, thiopentone, nitrous oxide–isoflurane anaesthesia. The pharmacodynamic profile of mivacurium-induced neuromuscular block was also evaluated at the two muscles using accelerometry.

Patients and methods

We studied 30 adult male patients, ASA I or II, aged 20–50 yr (mean 36.7 yr), weighing 61–82 kg (mean 68 (SD 9.4 kg), undergoing diagnostic endoscopic surgery, for example knee arthroscopy. This study was approved by the Hospital Ethics Committee and all patients gave written informed consent. We excluded any patient suffering from cardiac, vascular, respiratory, hepatic, renal or neuromuscular disorders. Chronic smokers, patients with previous head and neck surgery, history of small joint arthritis or those receiving medications known to affect normal neuromuscular transmission were also excluded.

All patient were premedicated with oral diazepam 10–15 mg, approximately 90 min before surgery. In the operating room, lactated Ringer's solution with 5% glucose was administered at a rate of 4–6 ml kg^{-1} h^{-1} via a peripheral arm vein. The ECG was monitored continuously and arterial pressure was measured using an electronic oscillotonometer. Anaesthesia was induced in all patients with midazolam 2–3 mg, fentanyl 2 μg kg^{-1} and thiopentone 4–5 mg kg^{-1}. The airway was maintained with an appropriately sized laryngeal mask. For the first 5 min after induction, anaesthesia was maintained with 70% nitrous oxide in oxygen. This was followed by addition of 0.5–1% isoflurane end-tidal concentration to the anaesthetic mixture. Ventilation was controlled to maintain normocapnia (end-tidal carbon dioxide partial pressure 4.6–5.3 kPa). Nasopharyngeal temperature was monitored and maintained at 36–37 °C using warm blankets and heated i.v. fluids. Skin temperature over the thenar eminence and the forehead was monitored also and maintained at 32–33 °C. Concentrations of isoflurane, nitrous oxide, carbon dioxide and oxygen saturation were measured continuously by a multiple-gas analyser (Capnomac Ultima-SVI, Datex Instrumentarium Corporation, Helsinki, Finland).

The ulnar and temporal branches of the facial nerves were stimulated supramaximally with single twitch square pulses of 0.2 ms duration, repeated every 10 s. An acceleration piezoelectric transducer (Biometer International, Odense, Denmark) was fastened to the volar surface of the distal phalanx of the thumb using adhesive tape or to the upper eyelid by means of double-sided adhesive tape. At the eyelid, the piezoelectric transducer was fixed such that it measured the acceleration generated by circumferential contraction of the orbicularis oculi muscle.[4]

After at least 20 min of stable anaesthetic conditions and stabilization of the twitch height recordings, each patient received an i.v. bolus of mivacurium 0.2 mg kg^{-1}. At maximum block, the pattern of nerve stimulation was changed to a train-of-four (TOF) sequence at 2 Hz repeated every 15 s. Recording of the evoked adductor pollicis or orbicularis oculi response was carried out using a TOF Guard neuromuscular monitor (Biometer International, Odense, Denmark). All graphical and numerical neuromuscular data were recorded on a memory card and subsequently a computer printout was obtained using TOF Guard Reader software (Biometer International, Odense, Denmark). The following variables were determined for each muscle: (1) maximum twitch depression after mivacurium; (2) onset of block: time interval between the end of injection of mivacurium and development of maximum block; (3) time interval between development of maximum block and recovery of T1 to a value of 25% and 75% of its control, and recovery of train-of-four ratio (T4/T1) to a value of 90%; (4) recovery index (RI): time required for recovery of T1 from 25 to 75% of its control; (5) T1 and train-of-four ratio every 1 min for at least 30 min after development of maximum block; (6) T4/T1 ratio at 10% incremental recovery of T1.

A laser Doppler flowmeter (Laserflo BPM², Vasamedics Inc, Minnesota, USA) was used to measure blood flow at either the adductor pollicis (n=15) or the orbicularis oculi muscle (n=15). A sterile 19-gauge needle type laser flowmeter probe (Laserflo BPM², Vasamedics Inc, Minnesota, USA) was inserted percutaneously in the thenar eminence or the orbital part of the orbicularis oculi muscle. The hand and eye contralateral to the site of neuromuscular monitoring were used for blood flow measurements. Blood flow monitoring started in all patients before induction of anaesthesia and 15 min were allowed for stabilization of the flow signal. The baseline awake blood flow value was obtained as the mean of three successive readings recorded at 2-min intervals. During the course of anaesthesia, muscle blood flow was monitored continuously and recorded every 1 min for the first 10 min during induction and every 5 min during maintenance of anaesthesia.

Statistical analyses were performed by analysis of variance (for repeated measures) to compare blood flow changes within each muscle, and paired Student's t test to compare the two muscles with respect to blood flow and neuromuscular data. Differences were considered significant when $P<0.05$.

Table 1 Neuromuscular data (mean (SD))

	Orbicularis oculi	Adductor pollicis	P
Maximum twitch depression (%)	96.4 (3.5)	100	ns
Onset (s)	130.4 (28.5)	202.7 (37.2)	<0.001
T1 25% (min)	9.1 (3.2)	12.9 (3.9)	<0.01
T1 75% (min)	16.2 (3.9)	21.1 (5.1)	<0.05
Recovery index (min)	7.1 (2.2)	8.2 (1.8)	ns
T4/T1 (90%) (min)	20.2 (4.3)	30.8 (7.4)	<0.001

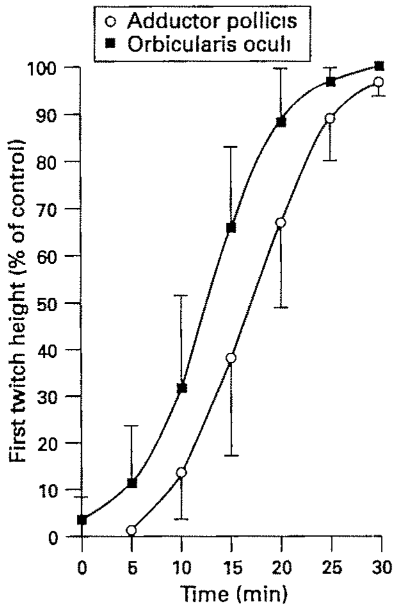

Figure 1 Time course of first twitch recovery at the orbicularis oculi and adductor pollicis muscles after mivacurium 0.2 mg kg^{-1} (mean, SD).

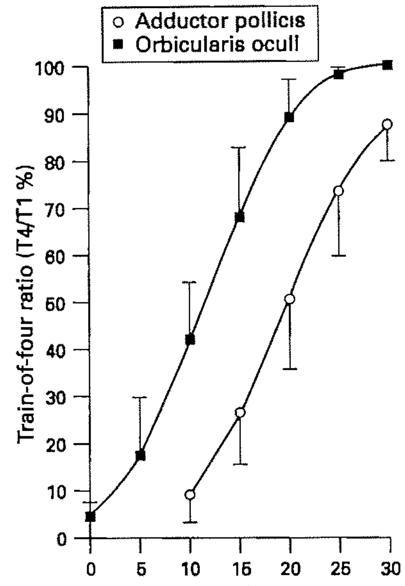

Figure 2 Time course of train-of-four ratio (T4/T1 %) recovery at the orbicularis oculi and adductor pollicis muscles after mivacurium 0.2 mg kg^{-1} (mean, SD).

Results

All patients developed 100% neuromuscular block at the adductor pollicis muscle. In contrast, neuromuscular block at the orbicularis oculi was 85–94% in seven patients. However, overall mean maximum neuromuscular block at the orbicularis oculi was 96.4 (SD 3.5) % and was not statistically different from the adductor pollicis muscle.

Onset time, time required for 25% and 75% recovery of T1, and T4/T1 ratio of 90% were all shorter for the orbicularis oculi than the adductor pollicis muscle. Recovery indices were comparable at the two muscles (table 1, figs 1, 2).

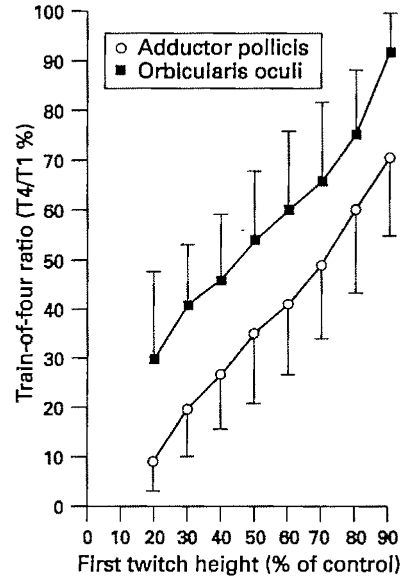

Figure 3 Relationship between first twitch recovery (% of control) and train-of-four fade (T4/T1) during recovery from mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles (mean, SD). There was significantly less T4/T1 fade at the orbicularis oculi than at the adductor pollicis muscle throughout the course of first twitch (T1) recovery.

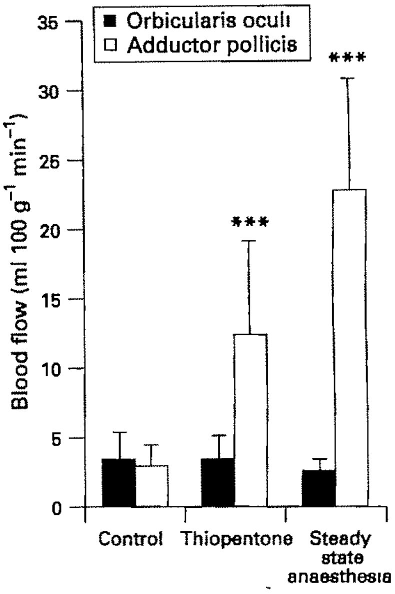

Figure 4 Blood flow pattern at the orbicularis oculi and adductor pollicis muscles before anaesthesia (control), after thiopentone, and during steady state isoflurane anaesthesia (mean, SD). ***$P<0.001$ compared with control values.

For a given T1, there was significantly less train-of-four fade (T4/T1) at the orbicularis oculi than at the adductor pollicis muscle throughout the course of neuromuscular recovery (fig. 3).

Blood flow was comparable at the two muscles before induction of anaesthesia. Thiopentone significantly increased thenar muscle blood flow from 2.9 (1.5) to 12.3 (6.8) ml 100 g^{-1} min^{-1}, with a further increase to 22.7 (8.0) ml 100 g^{-1} min^{-1} with addition of isoflurane ($P<0.001$). Blood flow at the orbicularis oculi was not altered by thiopentone or isoflurane and was consistently lower than that at the adductor pollicis muscle despite comparable haemodynamics in the two groups (fig. 4).

Temperature of the skin overlying the two muscles was comparable.

Discussion

We have confirmed the current view that the onset of non-depolarizing neuromuscular block is more rapid and its duration is shorter at the orbicularis oculi compared with the adductor pollicis muscle. The difference in onset time of mivacurium-induced block between the two muscles was, on average, 1.2 min. This is consistent with the recent findings of Rimaniol and collaegues[4] and Debaene and co-workers.[8] Onset times of neuromuscular block at the orbicularis oculi muscle reported by Rimaniol and co-workers[4], using accelerometry, were 235 and 90 s after mivacurium 0.15 mg kg^{-1} and 0.25 mg kg^{-1}, respectively. In our study, onset time of an intermediate dose of mivacurium 0.2 mg kg^{-1} at the orbicularis oculi was 130.4 s and was in general agreement with the trends in onset time reported by Rimaniol and colleagues.[4]

Neuromuscular blocking agents can only produce neuromuscular block when they bind with acetylcholine receptors at the neuromuscular junction. Therefore, onset time after injection of neuromuscular blocking drugs into a peripheral vein depends on circulatory factors, notably cardiac output, circulation time to the muscle, muscle blood flow and proximity of the target muscle to the central arterial circulation.[9,10] In this study the response of the orbicularis oculi and adductor pollicis muscles were determined simultaneously in the same group of patients. This clearly obviates the possible effect of cardiac output on the onset of block. A surprising finding in this study was that blood flow in the orbicularis oculi muscle was significantly lower than that in the adductor pollicis muscle during thiopentone–nitrous oxide–isoflurane anaesthesia. The underlying reasons for the differences in blood flow between the two muscles are unclear at this stage. However, Vollmar and Habazettl,[11] noted that the nature and magnitude of the vascular effects of anaesthetics vary depending on the vascular bed and type of vessels studied. Our blood flow results suggest that, at least for the orbicularis oculi muscle, blood flow was not the main mechanism of rapid onset of action of mivacurium-induced block. It is possible however that the proximity of the orbicularis oculi to the central circulation compared with the adductor pollicis may compensate for the difference in blood flow and may have a role in accelerating the onset of neuromuscular block at the former. The onset of vecuronium-induced neuromuscular block in the adductor pollicis muscle was more rapid when the drug was injected into the central circulation, via a pulmonary artery catheter, than when the drug was given into a peripheral vein on the hand [12].

In our study, all patients developed 100% neuromuscular block at the adductor pollicis muscle, but neuromuscular block at the orbicularis oculi was 85–94% in seven patients. These findings, coupled with a shorter duration of mivacurium-induced block at the orbicularis oculi, reflect the relative resistance of this muscle to mivacurium-induced block. Several mechanisms have been proposed to explain the unequal sensitivities of different muscles to neuromuscular blocking agents. Recent studies, however, proved that this is related mainly to mean muscle fibre diameter and the fraction of fibre circumference occupied by the motor endplate.[13] However, the association between duration of neuromuscular block and fibre size or endplate to fibre size ratio was relatively weak suggesting that other factors may contribute to muscle response to neuromuscular blockers.

Bowman[14] suggested that single twitch depression, and tetanic or train-of-four fade, are the result of interaction of acetylcholine antagonists with different binding sites within the neuromuscular junction. Neuromuscular blockers act at presynaptic nicotinic receptors in such a way that mobilization of acetylcholine is impaired. Thus during high frequency stimulation, transmitter output becomes exhausted so that fade occurs. In this study, there was significantly less train-of-four fade (T4/T1) at the orbicularis oculi than the adductor pollicis muscle throughout the course of neuromuscular recovery. It is therefore possible that resistance of the orbicularis oculi may reflect less prejunctional effects of mivacurium at this muscle than the adductor pollicis.

Current evidence suggests that interest is increasing in monitoring the response of orbicularis oculi muscle in clinical practice. This is mainly because of the comparable neuromuscular course at this muscle, the diaphragm and laryngeal muscles.[2] Force displacement transducers[15], electromyography[2] and visual assessment[8] have been used previously to monitor the orbicularis oculi response. Mechanomyography and electromyography are used mainly for research purposes. Visual assessment is simple but lacks reliability. The recent study by Rimaniol and colleagues[4] and our study have demonstrated that piezoelectric acceleration transducers could be used to monitor the mechanical response of the orbicularis oculi muscle. The new generations of acceleration monitors, for example TOF Guard, are as reliable as mechanomyography and electromyography[16,17] and their simplicity of operation may increase interest in routine neuromuscular transmission monitoring at different sites, including the orbicularis oculi muscle.

Comparison of extradural and general anaesthesia on the fibrinolytic response to total knee arthroplasty

N. E. SHARROCK, G. GO, P. WILLIAMS-RUSSO, S. B. HAAS AND P. C. HARPEL

Summary

Extradural anaesthesia is associated with lower incidences of deep vein thrombosis after total knee arthroplasty. It is not known if the type of anaesthesia influences thrombogenesis or fibrinolysis during knee surgery performed under tourniquet. We studied 31 patients allocated randomly to receive either extradural or general anaesthesia for primary unilateral total knee arthroplasty performed under tourniquet. Radial artery blood samples were obtained before surgery, during surgery with the tourniquet inflated and on deflation of the tourniquet. Plasma samples were assayed for markers of thrombin generation and fibrinolysis. Two of the circulating indices of thrombin generation, fibrinopeptide A and thrombin–antithrombin complexes, increased to a similar degree in the perioperative period in both groups. Fibrinolytic activity was similar in both groups, as measured by tissue plasminogen activator (t-PA) antigen, t-PA activity, t-PA–plasminogen activator inhibitor complexes, α_2-plasmin inhibitor–plasmin complexes and D-dimer. Extradural and general anaesthesia did not result in significant differences in either thrombin generation or fibrinolytic activity during total knee arthroplasty performed under tourniquet. (*Br. J. Anaesth.* 1997; **79**: 29–34).

Key words
Anaesthetic techniques, extradural. Anaesthesia, general. Complications, thrombosis. Blood, coagulation. Surgery, orthopaedic.

The incidence of deep vein thrombosis (DVT) after total knee arthroplasty is reported to be lower with extradural than general anaesthesia.[1–4] The mechanism for this reduction is not known but it has been proposed that extradural anaesthesia may be associated with enhanced fibrinolysis.[1 3 5] Increased fibrinolytic activity was demonstrated in patients receiving extradural anaesthesia for total hip arthroplasty[5] and peripheral vascular surgery[6] but other studies have failed to confirm this finding.[7 8]

We examined if fibrinolysis is enhanced in the immediate perioperative period as the majority of thrombi which develop after total knee arthroplasty are evident venographically immediately after surgery.[9] Contrary to our expectation, there were no differences in either indices of thrombin generation or fibrinolysis between extradural and general anaesthesia. These data suggest that the salutary effect of extradural anaesthesia on DVT after total knee arthroplasty may be caused by other factor(s) in this early postoperative period.

Patients and methods

After obtaining Institutional Review Board approval, 31 patients diagnosed with osteoarthritis undergoing unilateral primary bicondylar cemented total knee arthroplasty consented to be allocated randomly to receive either extradural or general anaesthesia. These were a subpopulation of patients enrolled in a larger study[4] designed to compare the effects of general with extradural anaesthesia on cognitive function, adverse cardiac events and DVT after total knee arthroplasty. Patients were excluded if they had any contraindication to either extradural or general anaesthesia. Contraindications to extradural anaesthesia included ankylosing spondylitis, history of extensive Harrington rod spinal fusion to the sacrum, cancer metastases to lumbar or thoracic vertebrae, history of bleeding diathesis and local infection at the site of extradural anaesthesia. Contraindications to general anaesthesia included a history of malignant hyperthermia and unstable cervical spine. Patients were also excluded if they had been receiving anticoagulants within 1 month of surgery.

All patients discontinued aspirin 1 week before surgery and other non-steroidal anti-inflammatory medication at least 48 h before operation. Perioperative heparin was not administered and pneumatic compression boots were not used. After operation, all patient received aspirin 325 mg twice daily as the only form of thromboprophylaxis. The first dose was administered at least 4 h after surgery after all blood samples had been obtained.

ANAESTHESIA

Patients received no premedication. I.v. cannulae were inserted the evening before surgery and crystalloid infused at 50–70 ml h^{-1} before operation; 20-gauge radial artery cannulae were inserted percutaneously under local anaesthesia and patients were monitored with ECG and pulse oximetry. Patients receiving general anaesthesia also had end-tidal carbon dioxide and oesophageal temperature monitoring.

At the discretion of the anaesthetist, extradural anaesthesia was performed by injection of 15–20 ml of either 0.75% bupivacaine ($n=12$) or 2% lignocaine with adrenaline 1:300 000 ($n=3$) via a 17-gauge Tuohy needle at the L3–4 or L2–3 interspace and an extradural catheter inserted. Intraoperative haemodynamic stability was maintained with i.v. fluid and, if necessary, intermittent injections of ephedrine 3–5 mg to maintain systolic arterial pressure in the range 110–120 mm Hg. All patients received nasal oxygen 2–5 litre min^{-1} throughout surgery.

General anaesthesia was induced using fentanyl 1–3 $\mu g\ kg^{-1}$, thiopentone 2–3 mg kg^{-1}, and vecuronium 8–10 mg to facilitate tracheal intubation. Anaesthesia was maintained using isoflurane and 70% nitrous oxide in oxygen, and fentanyl up to 1 $\mu g\ kg^{-1}\ h^{-1}$. Antagonism of neuromuscular block was performed in all patients at the end of surgery and the trachea of all patients was extubated before transfer to the post-anaesthesia care unit (PACU).

SURGERY

Each procedure was performed under tourniquet; the tourniquet was inflated after exsanguination of the limb with an Esmarch bandage. After fixation of components with methylmethacrylate, the tourniquet was deflated for several minutes to achieve haemostasis; the Esmarch bandage was reapplied and the tourniquet re-inflated. At the end of surgery, the tourniquet was again deflated after the dressings were applied. All patients underwent primary total knee arthroplasty using cemented bicondylar components.

MEASUREMENTS

Blood samples were obtained from the radial artery cannula via a three-way stopcock at the following times: before induction of anaesthesia (sample 1), 20 min after the start of the surgical procedure (sample 2), 45 s after deflation of the tourniquet at the end of surgery (sample 3) and 1 h after operation in the PACU (sample 4). Continuous infusion of 3 ml h^{-1} of a solution containing unfractionated heparin 4 u. ml^{-1} in normal saline was maintained throughout surgery. Samples were obtained after 4 ml were discarded to clear the arterial cannula and prevent haemodilution. No patient received any blood products during the study period.

ASSAYS

Samples were placed in citrated tubes (sodium citrate 0.13 mol $litre^{-1}$, 9:1 volume to volume) and centrifuged at 2000 *g* for 10 min at 4 °C. Plasma samples were stored immediately at −70 °C until ready for assay. Blood for fibrinopeptide A measurement was collected in tubes containing an anticoagulant solution, provided with the Asserachrom (Diagnostica Stago, Franconville, France) fibrinopeptide A kit and treated with bentonite twice before storing at −70 °C. Measurement of fibrinopeptide A (FPA), D-dimer, thrombin–antithrombin (TAT) complex, tissue plasminogen activator (t-PA) antigen and t-PA–plasminogen activator inhibitor-1 (t-PA–PAI-1) were measured by enzyme-linked immunosorbent assay using the respective Asserachrom kits (Diagnostica Stago, Franconville, France). t-PA activity was measured using a whole plasma assay specific for t-PA as described previously.[10 11] α_2-Plasmin inhibitor–plasmin complexes (PIP) were assayed by a method described previously.[11]

DATA ANALYSIS

Differences between groups were compared using *t* tests for continuous variables, chi-square for dichotomous variables or the Mann–Whitney test for ordinal data. Differences in circulating haematological variables between groups were assessed using ANOVA, whereas paired *t* tests were used for within-group analysis. Alpha was set at 0.05.

Results

Preoperative characteristics and operative factors for patients receiving extradural anaesthesia ($n=15$) or general anaesthesia ($n=16$) were similar (table 1).

Fibrinopeptide A (FPA) (fig. 1) increased during surgery (samples 1–2) ($P=0.02$ and $P=0.07$) and

Table 1 Patient characteristics, surgery start time, duration of surgery and intraoperative i.v. fluids administered (mean (SD) or range) or number). No significant differences between groups

	General anaesthesia ($n=16$)	Extradural anaesthesia ($n=15$)

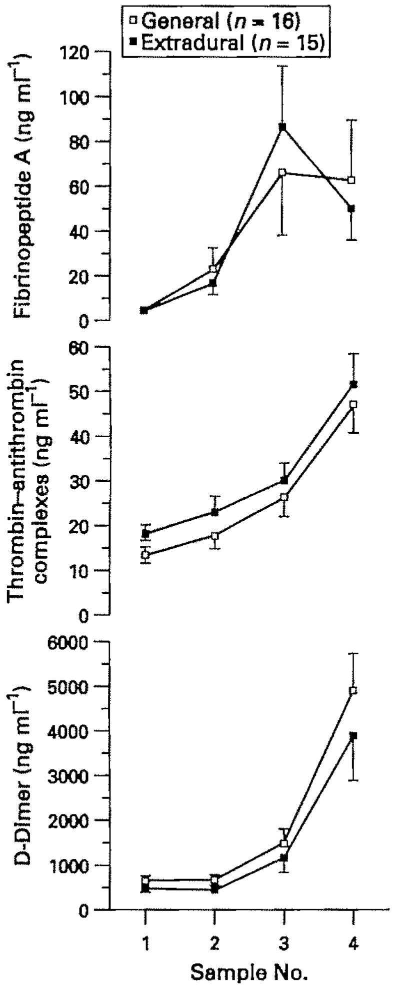

Figure 1 Fibrinopeptide A, thrombin–antithrombin complexes and D-dimer concentrations in patients receiving general or extradural anaesthesia. Measurements were made before induction of anaesthesia (sample 1), 20 min after the start of surgery (sample 2), 45 s after deflation of the tourniquet at the end of surgery (sample 3) and 1 h after operation in the PACU (sample 4). Values are mean (SEM).

also after deflation of the tourniquet at the end of surgery (samples 1–3) (P=0.01 and P=0.04) in the extradural and general anaesthesia groups, respectively. There were no significant differences between groups.

Thrombin–antithrombin complexes (TAT) (fig. 1) increased slightly during surgery with the tourniquet inflated (samples 1–2) (P=0.15 and P=0.05), but increased significantly after tourniquet deflation (samples 1–3) (P=0.002 and P=0.004) and remained increased at 1 h after surgery (samples 1–4) (P=0.0001 and P=0.0001) in the extradural and general anaesthesia groups, respectively. There were no significant differences between groups.

D-dimer (fig. 1) did not change significantly during surgery with the tourniquet inflated, but did increase significantly after deflation of the tourniquet (samples 1–3) (P=0.05 and P=0.01) and remained increased at 1 h after surgery (samples 1–4) (P=0.006 and P=0.0001) in the extradural and general anaesthesia groups, respectively. There were no significant differences between groups.

Tissue plasminogen activator (t-PA) activity (fig. 2) increased significantly with the tourniquet inflated (samples 1–2) (P=0.01 and P=0.01) and remained increased after tourniquet deflation (samples 1–3)

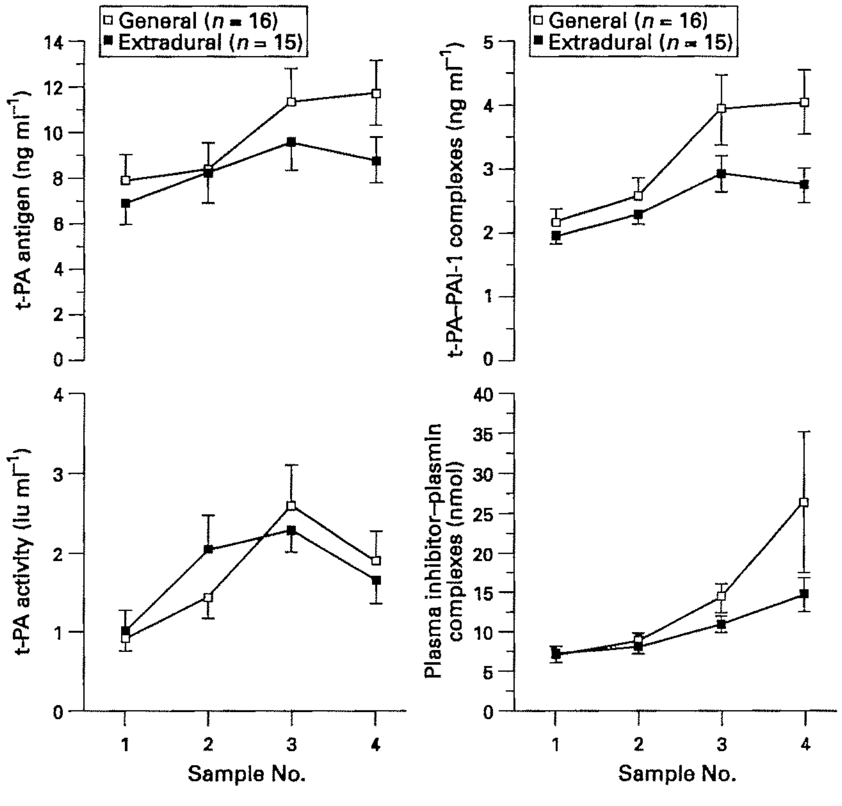

Figure 2 Tissue plasminogen activator (t-PA) antigen, t-PA activity, t-PA–plasminogen activator inhibitor-1 (t-PA–PAI-1) and α_2-plasmin inhibitor–plasmin complexes in patients receiving general or extradural anaesthesia Measurements were made before induction of anaesthesia (sample 1), 20 min after the start of surgery (sample 2), 45 s after deflation of the tourniquet at the end of surgery (sample 3) and 1 h after operation in the PACU (sample 4). Values are mean (SEM).

(P=0.0001 and P=0.001) in the extradural and general anaesthesia groups, respectively. t-PA activity declined after operation (samples 3–4) (P=0.03 and P=0.19) in the extradural and general anaesthesia groups, respectively. There were no differences between the extradural and general anaesthesia groups at any times.

Tissue plasminogen activator (t-PA) antigen, t-PA–plasminogen activator inhibitor (t-PA-PAI-1) complexes and α_2-plasmin inhibitor–plasmin (PIP) complexes (fig. 2) increased minimally with the tourniquet inflated (samples 1–2) but increased significantly after deflation of the tourniquet at the end of surgery (samples 1–3) (P<0.05). There were no significant differences between the extradural and general anaesthesia groups at any times.

The sample size of this study was sufficient to detect a significant difference in both FPA and t-PA activity equal to or greater than the SD of each measurement with a power of 0.8.

Discussion

All previous studies have shown a tendency for lower incidences of DVT in patients receiving extradural rather than general anaesthesia after total knee arthroplasty. In a small study from Sweden, incidences were 59% with general anaesthesia and 18% with extradural anaesthesia.[1] In a large retrospective study, incidences were 56% with general anaesthesia and 42% with extradural anaesthesia.[3] In a randomized, prospective study of extradural compared with general anaesthesia from which these patients were a subset, there was also a tendency towards a lower incidence of DVT with extradural anaesthesia (40% *vs* 48% for general anaesthesia).[4]

This study was designed to determine if differences in anaesthetic technique influenced the genesis of thrombosis during surgery itself. When thrombin, a serine protease, acts on fibrinogen to form fibrin, a cleavage product, fibrinopeptide A (FPA) is formed. When formed, circulating thrombin is subsequently bound to antithrombin III to form the inactive thrombin–antithrombin complexes (TAT). Concentrations of TAT and FPA are thus circulating indices of thrombin generation.[12 13] We reasoned that if more incidences of venous thrombosis were occurring during operation in patients receiving general anaesthesia, increased concentrations of FPA or TAT, or both, would be detectable in blood immediately after deflation of the tourniquet. Enhanced thrombogenesis was not observed in patients receiving general anaesthesia under tourniquet during surgery, as FPA and TAT concentrations were similar to those patients receiving extradural anaesthesia.

Immediately after the tourniquet was deflated (sample 3), significant increases in FPA and TAT were noted in both groups. These increases in TAT and FPA indicate that activation of the coagulation cascade was occurring during surgery with the tourniquet inflated and is confirmatory evidence that thrombi develop during total knee arthroplasty with the tourniquet inflated.[9 14]

Other studies have confirmed that thrombi develop in the intraoperative period during total knee arthroplasty with the tourniquet inflated. Parmet and colleagues observed showers of small emboli in the right atrium after tourniquet deflation using transoesophageal echocardiography.[14 15] Concurrently, they aspirated fresh thrombi from the femoral vein of the operated limb and from central venous catheters. Maynard, Sculco and Ghelman demonstrated that 86% of patients who went on to develop DVT after total knee arthroplasty had venographically evident thrombi in the immediate postoperative period.[9] Venous stasis,[16] hypoxia[17 18] and hypothermia led to endothelial injury in the ischaemic limb with the tourniquet inflated[19] providing an ideal nidus for DVT during total knee arthroplasty.

t-PA is released from endothelial cells and promotes the formation of plasmin from circulating plasminogen. Plasmin cleaves cross-linked fibrin into fibrin degradation products, which include D-dimer. Plasmin is inactivated by binding to an inhibitor to form α_2-plasmin inhibitor–plasmin complexes (PIP). Similarly, t-PA is inactivated by its inhibitor, plasminogen activator inhibitor (PAI-1), to form t-PA–PAI-1 complexes. t-PA activity represents the net excess of t-PA antigen over inhibitor activity.[20]

During surgery, there is typically enhancement of t-PA activity because of release of t-PA antigen. However, after operation, there is a so-called fibrinolytic shutdown as a result of an increase in PAI-1 release.[21 22] Our results are consistent with this pattern in patients undergoing total knee arthroplasty under both extradural and general anaesthesia. It has been proposed that venous thrombogenesis is more common in patients who have increased PAI-1 concentrations or in patients with suppression of fibrinolysis after operation.[6 23] We found no evidence that the type of anaesthesia influenced fibrinolytic activity in the immediate perioperative period.

It has also been stated that a salutary effect of extradural anaesthesia on fibrinolysis may be caused by concurrent use of adrenaline or ephedrine,[5] as these agents are known to augment t-PA release in young individuals.[24 25] In this study, patients in the extradural anaesthesia group received exogenous adrenaline or ephedrine, or both. In spite of this, no increase in t-PA activity or antigen concentrations was noted in the extradural anaesthesia group. This verifies our previous observation that low-dose adrenaline infusions do not augment t-PA activity in elderly patients during total hip arthroplasty.[26]

Modig and colleagues described more pronounced suppression of fibrinolysis after operation in patients who had general rather than extradural anaesthesia for total hip arthroplasty.[27] Others studying total hip arthroplasty[7 8] or hysterectomy[28] have been unable to repeat this observation. Perhaps the findings of Modig and co-workers could be caused by significant blood loss in their patients who received general anaesthesia (1600 ml),[27] whereas in other studies, intraoperative blood losses were less. In one study which showed no effect of type of anaesthesia on circulating indices of thrombosis and fibrinolysis, eye surgery was studied to eliminate the problem of blood loss and haemodilution.[29] Furthermore, the earlier studies demonstrating enhanced fibrinolysis with extradural anaesthesia used euglobulin lysis time to measure fibrinolytic activity.[27 30] Subsequent studies measuring t-PA activity, t-PA antigen or PIP have shown no differences.[7 8 28 29] Our results further demonstrate that the anaesthetic technique does not affect fibrinolysis when specific assays are used.

Prolongation of extradural analgesia after operation has been advocated as a means of maximizing the potential benefit of extradural anaesthesia on thrombogenesis by either increasing lower extremity blood flow[5 31] or by minimizing postoperative fibrinolytic shutdown.[6] This study did not examine this issue as samples were obtained in the immediate perioperative period. However, retrospective studies have failed to demonstrate any reduction in DVT rate after total knee arthroplasty when using long-acting local anaesthetics (bupivacaine *vs* lignocaine) or when postoperative extradural analgesia is used (compared with i.m. opioids).[32] Ideally, strategies to limit DVT should be initiated before or during surgery[33] as thrombi initially form during operation.[9 34] When thrombi are formed, postoperative therapy can only limit propagation and must rely on intrinsic fibrinolysis to clear them.

This study suggests that the mechanism which results in lower incidences of DVT after total knee arthroplasty using extradural anaesthesia is most likely acting after operation rather than during surgery. Davis and colleagues noted that lower extremity blood flow is increased in the early postoperative period in patients receiving spinal rather than general anaesthesia.[31] Enhanced blood flow may wash out loosely formed thrombi or limit early propagation of existing thrombi. Alternatively, extradural anaesthesia or analgesia may enhance rates of rehabilitation.[35] In the randomized study of 262 patients from which this is a subset, we noted that patients receiving extradural anaesthesia achieved certain rehabilitation milestones earlier than the general anaesthesia group.[4] Perhaps earlier ambulation with extradural anaesthesia reduces DVT by improving deep venous blood flow. In this regard, it is known that mechanical devices such as pneumatic compression stockings[36] or Plexipulse (foot pump),[37] which augment blood flow in the calf, reduce DVT rates after total knee arthroplasty by 40–50%.[36 37]

Cardioventilatory coupling during anaesthesia

D. C. GALLETLY AND P. D. LARSEN

Summary

In 20 spontaneously breathing patients undergoing minor surgical procedures under general anaesthesia, we examined the timing relationship of heart beat and ventilation. Patients received propofol 2–2.5 mg kg^{-1} and fentanyl 1 μg kg^{-1} and breathed a mixture of 1–1.5% isoflurane and 66% nitrous oxide in oxygen. We recorded ECG R wave times and the start of each inspiration. We observed that: (1) all subjects showed evidence of phase coupling in which heart beats occurred at constant phases of the ventilatory cycle; (2) there was a significant preference for whole number ratios of heart rate to ventilatory frequency; (3) phase coupling was associated frequently with quantal changes in heart rate or ventilatory frequency, or both; (4) six coupling patterns were described according to the timing relationship between the ECG R wave and start of inspiration and according to changes in the number of heart beats within each ventilatory period; (5) phase coupling was achieved primarily by transient changes in ventilatory period. Phase coupling, in concert with respiratory sinus arrhythmia, may optimize the performance of the thoracic pump, matching cardiac filling to venous return. Coupling may therefore have anaesthetic relevance in conditions of impaired cardiac performance or hypovolaemia. (*Br. J. Anaesth.* 1997; **79**: 35–40).

Key words

Heart, heart rate. Ventilation, frequency. Monitoring, electrocardiography. Monitoring, ventilation. Cardiorespiratory system, effects.

Heart rate variability is a consequence of periodic fluctuations in sympathetic and parasympathetic outflow to the heart. Baroreflex inputs to autonomic neurones within the brainstem modulate this efferent activity and, in turn, ventilation modulates the degree to which these baroreceptor inputs influence the firing of autonomic neurones. Respiratory sinus arrhythmia is the result of this ventilatory modulation.

In addition to sinus arrhythmia, heart beats may become "phase coupled" to respiration, such that heart beats occur at constant phases of the respiratory cycle. Although this coupling is poorly seen in alert and active human subjects, it is clearly present during sedation,[1] sleep[2] and in conditions of low cognitive and behavioural activity.[3]

Cardioventilatory coupling in mammals was first described by Walter Coleman in 1921 after experiments performed at the London Zoological Gardens in Regents Park. In one of several classic articles[4 5] he describes how: "The movements of the whiskers of a resting leopard were perfectly regular and indicated its heart rate as 54. The metronome was set at that rate with subdued sound, and expansions of the lungs ceased at strokes of metronome as follows: 5, 5, 5, 6, 5, 5, 5, 6, 5, 5, 5, 6, 3. The animal stirred at 3. This and many other tests indicate that usually with animals at rest and always during sleep the breath begins at multiples of the heart-rate".

In humans, cardiorespiratory synchronization was first described by Galli in 1924.[6] In subsequent years the subject was largely forgotten until, from the 1950s, groups of German physiologists (Hildebrandt, Bucher, Engel, Raschke, Kenner and others)[2 3 6–10] attempted to further define the interaction and determine its mechanism. The subject of cardioventilatory phase coupling is largely confined therefore to German language publications and despite its possible relevance, the anaesthesia literature is devoid of discussion on the subject.

In 1972, Engel, Jaeger and Hildebrandt,[7] using statistical methods, demonstrated the presence of phase coupling in anaesthetized adults and children. Since then advances in computer-based digital signal processing and graphical analysis techniques have made it possible for a more detailed examination of the phenomenon. In this study we sought to further define the frequency and nature of cardioventilatory coupling in patients undergoing surgical procedures under general anaesthesia.

Patients and methods

After obtaining Ethics Committee approval, we studied 20 consenting, unpremedicated ASA I and II adult patients undergoing elective orthopaedic or gynaecological surgery. None was taking regular medications or had evidence of cardiorespiratory disease.

Anaesthesia was induced with propofol 2–2.5 mg kg^{-1} and maintained by spontaneous inhalation of

D. C GALLETLY, MB, CHB, FRCA, FANZCA, P. D. LARSEN, BSC (HONS), Section of Anaesthesia, Wellington School of Medicine, PO Box 7343, Wellington, New Zealand. Accepted for publication: February 26, 1997.

1–1.5% isoflurane and 66% nitrous oxide in oxygen. After induction, a laryngeal mask was inserted and increments of fentanyl 50–100 μg or morphine 5–10 mg were given as required. In two patients, vecuronium was administered for neuromuscular block and in these, mechanical IPPV was applied to give an end-tidal carbon dioxide partial pressue of 4.7–5.3 kPa. In both patients, spontaneous ventilation recordings were obtained before neuromuscular block.

We monitored arterial oxygen saturation (Sp_{O_2}), end-tidal carbon dioxide concentration, end-tidal isoflurane concentration (Datex AS3), heart rate, ECG (lead CM_5, Corometrics Neo-Trak 502) and timing of inspiration.

Ventilatory timing was measured by incorporating a Ruben non-return valve into the T of the circle absorption system. The valve was modified by addition of a photodetector and light beam across the path of the valve shuttle. This generated a 1.5-V square wave signal while the valve was open (i.e. from start inspiration to end inspiration). Using this system a small delay may be expected from the onset of inspiration until opening of the valve shuttle, however, we considered this delay small in comparison with the duration of a heart period.

For a minimum of 5 min, ECG and photodetector output were recorded continuously using a Macintosh IIcx computer with 16 bit ADC board (National Instruments) and a sampling rate of 500 Hz. Recording of cardioventilatory data began after laryngeal mask insertion and continued until the end of surgery.

ANALYSIS

Analysis of phase coupling was based on the method described by Kenner, Pessenhofer and Schwaberger.[8] From the stored ECG data, we measured the time of each R wave peak and, from the ventilatory signal, we determined the time of each inspiratory onset. From these data, we calculated the interval between each R wave and the following, in addition to the preceding, start of inspiration (RI intervals). RI intervals for each heart beat were then plotted against time of R wave occurrence (RI plot). RI intervals for R waves preceding the inspiration were given a negative subscript and RI intervals after an inspiration were given a positive subscript: RI_{-1} for the beat preceding the inspiration and RI_{+1} , RI_{+2}, etc, for beats after the inspiration

A fixed relationship, or coupling, between heart beats and inspiration is revealed in an RI plot as horizontal banding in which values of $RI_{\pm n}$ maintain relatively constant values over time.

In addition to calculating RI intervals, we determined the degree to which heart rate and ventilatory frequency approached a whole number ratio. We calculated for all time series and for each breath the ratio of heart rate to ventilatory frequency where heart rate was calculated from the median of seven consecutive beats. Integer preference (IP) was defined as a heart rate to ventilatory frequency ratio subtracted from its closest integer value (a ratio of 3.67 becomes 3.67−4=−0.33, a heart rate to ventilatory frequency ratio of 5.01 becomes 5.01−5=0.01). The mean absolute value (|IP|) of this integer preference was calculated for each subject. |IP| values close to 0 indicate an integer ratio.

As a measure of respiratory sinus arrhythmia we took a representative 256-s, artefact-free segment of the RR interval time series. Using previously described methods we performed a fast Fourier analysis on this segment.[11] A measure of ventilatory heart rate modulation was determined by calculating the area under the power spectrum curve between 0.15 and 0.4 Hz.

Statistical analysis was performed only on spontaneously breathing segments in those patients who subsequently underwent artificial ventilation.

All software was purpose written in LabView 2 (National Instruments).

Results

Mean patient age was 39 (range 18–66) yr; 15 were female and mean duration of data recording was 23 (range 6–70) min. Cardioventilatory coupling was observed in all patients. A representative example of data obtained from one subject is shown in figure 1.

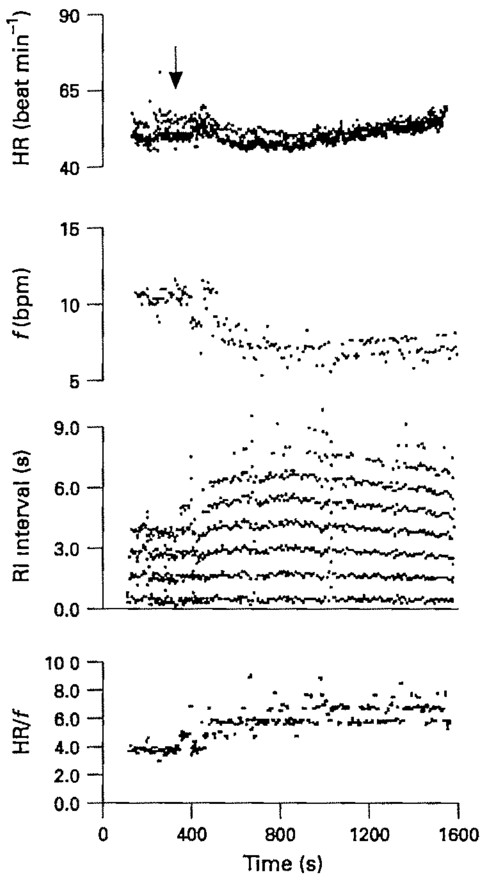

Figure 1 Representative data from one spontaneously breathing patient. Fentanyl 50 μg i.v. was given at 400s (arrow). Beat-to-beat heart rate (HR), breath-to-breath ventilatory frequency (*f*), RI interval and heart rate/ventilatory frequency ratio (HR/*f*) are shown. The RI plot shows horizontal banding indicating cardioventilatory coupling. The increase in number of bands reflects the increasing number of RI intervals per breath as ventilatory frequency decreases after administration of the opioid. Note quantal changes in HR and *f* (shown as banding of their individual time series) and whole number steps in HR/*f* ratio.

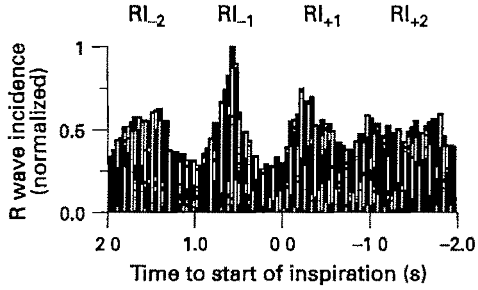

Figure 2 Histogram of R wave occurrence, relative to start of inspiration, normalized and averaged for all subjects.

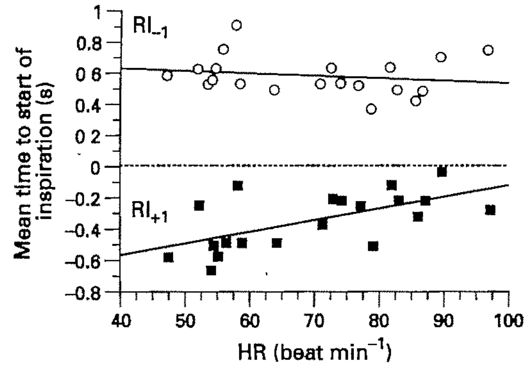

Figure 3 Mean RI$_{-1}$ and RI$_{+1}$ for 20 subjects *vs* mean heart rate (HR). Note the relative constancy of RI$_{-1}$ independent of RR interval (heart rate)

R WAVE ALIGNMENT TO INSPIRATION

Figure 2 is an averaged and normalized histogram of RI intervals for all subjects and shows a peak R wave incidence, corresponding to RI$_{-1}$, at 0.5 s before the start of inspiration. The peak corresponding to RI$_{+1}$ was less apparent as were other R wave alignments. Thus relative to start inspiration, RI$_{-1}$ was the least variable R wave position. Mean RI$_{-1}$ values for all subjects were 0.51 (SD 0.1) s. Mean RI$_{+1}$ inversely correlated with mean heart rate ($P<0.005$) whereas the correlation between mean RI$_{-1}$ and heart rate was not statistically significant (fig. 3).

QUANTAL HEART RATE AND VENTILATORY FREQUENCY ADJUSTMENTS

Both heart rate and ventilatory frequency were observed to fluctuate at times in a quantal manner. This appeared as banding of the beat-to-beat heart rate (or RR interval) and breath-to-breath ventilation rate time series (fig. 1).

Quantal heart rate changes were observed only during periods of cardioventilatory phase coupling. At these times, because R waves occurred at roughly constant intervals after the start of inspiration, RI$_{+1}$ was influenced differently by vagal withdrawal than RI$_{+2}$, RI$_{+3}$, and so on (fig. 4). Thus the RR interval after inspiration was shorter than subsequent intervals giving a banded appearance to the heart rate time series. The width of these bands varied depending on the degree of respiratory sinus arrhythmia.

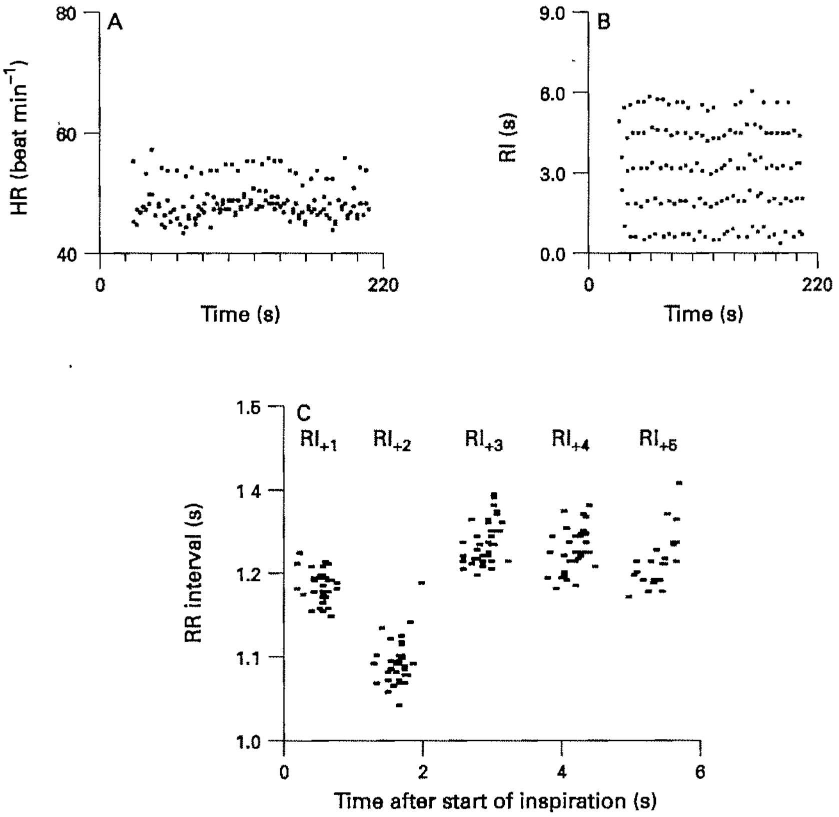

Figure 4 A: Heart rate (HR) time series, B: RI plot and C: RR interval plotted against time after start of inspiration. Note the quantal changes in HR (shown as banding of the HR time series) as a result of the greater degree of vagal withdrawal imposed on RI$_{+1}$ compared with RI$_{+2}$ RI$_{+3}$, RI$_{+4}$ and RI$_{+5}$.

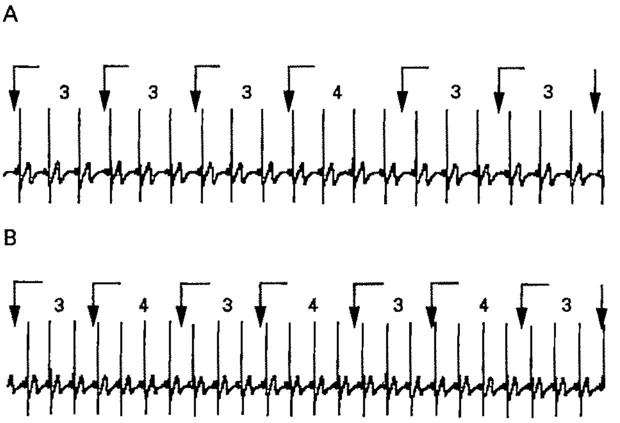

Figure 5 ECG and ventilation in one subject showing; A: a single prolongation in ventilatory period during a synchronized pattern of constant 3:1 ratio coupling; B: alternating 3:1, 4:1 coupling with alternating RI interval, also shown in figure 8D. Arrow indicates start inspiration and horizontal bar the duration of inspiration, numbers refer to heart beats within each ventilatory period.

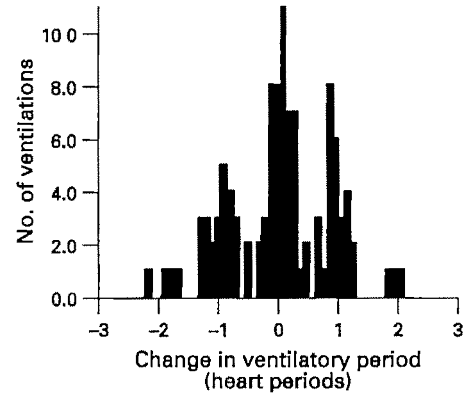

Figure 6 Histogram of breath-to-breath change in ventilatory period as a multiple of the heart period. Data were taken from the subject of figure 1 and show that changes in ventilatory period were frequently in one heart period steps.

Quantal changes were also observed in ventilation. The banded appearance in a ventilation rate time series is seen in figure 1. The quantal change in ventilatory frequency corresponds to transient rate fluctuations as ventilation jumps between different heart rate to ventilatory frequency integer ratios while heart rate is relatively constant. An example is seen in figure 5A where 3:1 coupling is interrupted by a single 4:1 coupling. Because the ventilatory period is extended by approximately one heart period, the observed ventilatory frequency time series banding width (fig. 1) corresponds to approximately one heart period. The histogram in figure 6 shows the distribution of ventilatory periods measured as a multiple of the heart period in one subject and demonstrates the quantal ventilatory adjustments at multiples of the heart period.

INTEGER PREFERENCE

Synchronized coupling, where the heart rate to ventilatory frequency ratio (and number of heart beats within each ventilatory period) remained a constant whole number for periods longer than 60 s, was observed in 50% of subjects. The mean |IP| for all subjects was 0.21 (0.07). This was significantly different ($P<0.05$; Student's t test) from a mean of 0.25 which would be expected if there was no preference for integer or non-integer ratio. Figure 7 shows the histogram of IP values averaged and normalized for all subjects; a clear peak at IP=0 is seen. Rapid transitions between integer ratios are also seen in the heart rate to ventilatory frequency ratio plot of figure 1 and in figure 5.

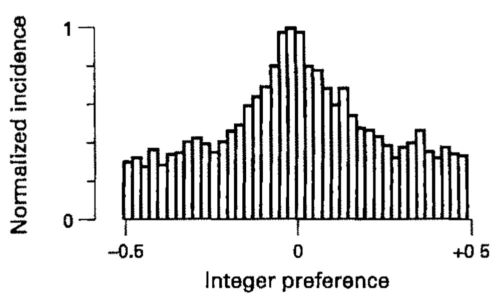

Figure 7 Histogram of integer preference, normalized and averaged for all subjects.

Although we observed the expected diminution of respiratory sinus arrhythmia with age (correlation between area under the ventilatory portion of the RR interval spectrum and age, $P<0.05$), the presence of coupling (RI plots) appeared unaffected and there was no correlation between age and integer preference (mean |IP|).

PATTERNS OF COUPLING

A variety of coupling patterns were observed in the RI plots with subjects commonly showing transition from one to another.

(a) Synchronous coupling (fig. 8A) with constant RI alignments and a strict whole number heart rate to ventilatory frequency ratio. This was observed, for periods longer than 60 s, in 10 (50%) subjects.

(b) Uncoupled with unstructured RI plots (fig. 8B). This was seen in only two (10%) subjects both of whom demonstrated high degrees of respiratory sinus arrhythmia.

(c) Uncoupled with slowly changing RI alignments (fig. 8C). This was observed during periods of intermittent positive pressure ventilation (two of two subjects) and for short periods in six (30%) spontaneously breathing subjects.

(d) Non-synchronous coupling with double banding of the RI plot (fig. 8D). RI intervals for one breath were similar to those two breaths in advance, however consecutive breaths had different RI intervals. Ventilatory period and heart rate to ventilatory frequency ratio alternated between two values. The jumps in ventilatory period were not exactly equal to one heart period, thus RI alignment is slightly different for alternate breaths. This pattern was seen in six subjects (30%). An example is shown in figure 5B.

(e) Coupling with a similar appearance to synchronized coupling but with a varying number of heart beats within each ventilatory period (fig. 8E). This common pattern (100% of subjects) occurred where the heart rate to ventilatory frequency ratio

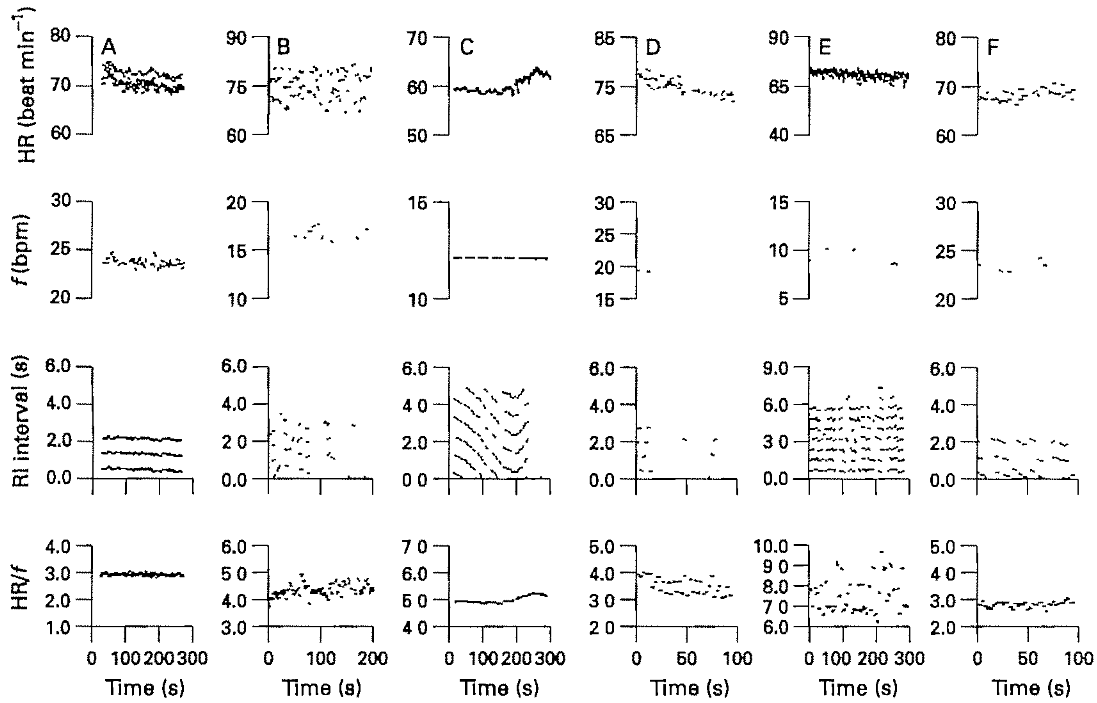

Figure 8 Six observed patterns of cardioventilatory coupling. For each coupling pattern, the figure shows beat-to-beat heart rate (HR), breath-to-breath ventilatory frequency (*f*), RI interval and heart rate/ventilation rate ratio (HR/*f*)

varied but quantal changes in ventilatory period allowed synchronization of R waves to inspiration for each breath.

(f) Non-synchronous coupling with slurring of the RI plot at preferred RI alignments was seen in five (25%) subjects. In figure 8F heart rate and ventilatory frequency are a little out of whole number ratio and RI_{-1} values gradually change away from the preferred 0.5 s. As the RI_{-1} value approaches 0 however, a rapid change in ventilatory periods brings the RI value back to the preferred alignment.

Discussion

In this study we observed cardiorespiratory phase coupling in all of our spontaneously breathing anaesthetized subjects. Although the specific pattern of coupling varied between subjects, and over time, it was rare to observe complete absence.

In order to achieve synchronization of the heart rhythm with ventilation, adjustments to either heart beat timing or ventilation, or both, must occur. We observed that constancy of RI intervals was most pronounced for the R wave immediately preceding inspiration rather than that which follows. RI_{-1} therefore was the most constant RI interval. This suggests that start of inspiration is triggered by an event associated with the preceding heart beat. As fluctuations in RR interval caused by respiratory sinus arrhythmia (fig. 4) occurred only after the start of inspiration, it is likely that these RR fluctuations are of little importance for RI alignment and therefore it is the inspiratory onset itself which is being adjusted to the preceding heart beat. These ventilatory adjustments were seen in our previous study of midazolam sedated patients and in this study (fig. 1) where ventilatory period jumped in a quantal manner to maintain RI alignment despite changing numbers of R waves within each ventilatory period. Kenner, Pessenhofer and Schwaberger[8] noted in rabbits that coupling was achieved by rapid and transient fluctuations in ventilatory frequency and observations of Hinderling,[10] in 1967, that coupling persists in patients with artificial cardiac pacemakers, clearly indicates the importance of modulation of ventilatory period. Quantal ventilatory frequency changes were first noted in anaesthesia by Goodman,[12 13] who ascribed the phenomena to a central multifrequency oscillator.

Afferent cardiovascular input which triggers phase shifts in ventilatory timing are not known with certainty. In experimental animals, coupling is abolished by vagotomy[8] and deafferentation of vagal fibres from the right atrium[14] and persists in the presence of artificial cardiac pacing and artificially induced pulsatile carotid flow.[9] Thus, afferent baroreceptor or atrial stretch receptor information, or both, is probably important in mediating phase coupling.

Control of cardioventilatory timing is thus a balance between respiratory sinus arrhythmia, achieved through heart rate adjustment, and phase coupling achieved through ventilatory adjustment. The relative importance of each however may vary depending on the subject and condition. It is known that with increasing age, respiratory sinus arrhythmia diminishes, whereas we observed no effect of age on coupling or integer preference. In contrast, sinus arrhythmia persists at all levels of cognitive arousal, whereas phase coupling is seen best during relaxation, sleep and anaesthesia.

It is traditionally believed that the increase in heart rate during inspiration (respiratory sinus arrhythmia) is of practical importance. As the negative intrathoracic pressure of inspiration causes increased venous return, vagolysis during the inspiratory period augments the performance of this "thoracic pump" and, with the Starling mechanism, helps match cardiac output to venous return. It is possible that cardioventilatory phase coupling may optimize the thoracic pump further. The R wave occurs approximately 0.5 s before the onset of inspiratory airflow. At inspiration therefore, ventricular ejection has occurred and the AV valves are opening, allowing rapid ventricular filling. In the presence of phase coupling, ventricular filling occurs at the same time that venous return is increasing as a result of negative intrathoracic pressure. Because of vagal withdrawal caused by respiratory sinus arrhythmia, a shortened RR interval occurs for the next heart beat allowing further filling and ejection of the heart during the inspiratory period. Thus phase coupling, in concert with sinus arrhythmia and the Starling mechanism, may optimize matching of venous return and cardiac filling.

In summary, respiratory sinus arrhythmia and cardioventilatory phase coupling together contribute to the timing of breathing and heart beats during anaesthesia. The phenomenon is readily apparent to the anaesthetist if excursions of the breathing bag and ECG tone are compared in spontaneously breathing patients. Observation of this link between breathing and heart beats clearly indicates the intimate relationship between cardiac and ventilatory dynamics.

Effect of domperidone on the ventilatory response to transient hyperoxia in patients anaesthetized with isoflurane

I. T. FOO, P. M. WARREN AND G. B. DRUMMOND

Summary

We have studied the ventilatory responses to transient hyperoxia in two groups of patients (n=10) anaesthetized with isoflurane (0.3 MAC); patients were allocated randomly to receive either domperidone or placebo orally before anaesthesia. In each patient, five two-breath oxygen tests were averaged and minute ventilation ($\dot{V}\text{E}^{\text{inst}}$) or mean inspiratory flow rate ($V\text{T}/T\text{I}$) for each post-test breath was compared with the mean values for these variables during baseline ventilation. A decrease to less than the 95% confidence limits of mean baseline values was considered a definite response. According to this definition, transient hyperoxia decreased $\dot{V}\text{E}^{\text{inst}}$ in nine of 10 patients in the placebo group and in all patients in the domperidone group. Similar changes occurred in $V\text{T}/T\text{I}$, with eight of 10 definite responses in the placebo group and 10 of 10 in the domperidone group. Compared with placebo, in the domperidone group there were larger changes in $\dot{V}\text{E}^{\text{inst}}$ (0.30 *vs* 0.55 litre min^{-1} (P=0.05)) and $V\text{T}/T\text{I}$ (8.5 *vs* 26.6 ml s^{-1} (P=0.02)) from respective baselines. Peripheral chemoreceptors appeared to be active during isoflurane anaesthesia and domperidone pretreatment enhanced this activity by increasing respiratory drive. (*Br. J. Anaesth.* 1997; **79**: 41–46).

Key words
Anaesthetics volatile, isoflurane. Pharmacology, domperidone. Reflexes, chemoreceptors. Ventilation, spontaneous. Ventilation, hypoxic response.

Knill and co-workers have shown that the ventilatory response to hypoxia (HVR) in humans is easily depressed by volatile anaesthetics.[1–3] Anaesthetic concentrations of halothane, enflurane and isoflurane virtually abolished HVR and even subanaesthetic concentrations of these agents reduced the response considerably. However, recent studies have shown that HVR is not as sensitive to isoflurane and ventilatory response to hypoxia remained in patients anaesthetized with 0.6–1.1 MAC of isoflurane.[4–6] Animal studies also provide conflicting data as to whether or not HVR is depressed by volatile anaesthetics.[7 8]

The site of action of volatile agents on HVR remains unclear. Limited studies in humans suggest that the carotid bodies are the most likely site of action.[9–11] However, the peripheral chemosensors appear to be active during light halothane anaesthesia. Clergue and co-workers[12] used a method derived from Dejours' test to assess the response to hypoxia from the transient decrease in ventilation after oxygen was substituted for room air, where the time course of response indicates a rapid (peripheral) reflex.

We have assessed if peripheral chemoreceptors are active during isoflurane anaesthesia by observing ventilatory responses to transient hyperoxia during light isoflurane anaesthesia. This test, derived from Dejours' test, is based on the concept that the initial response to hyperoxia (transient ventilatory depression) is mediated by peripheral chemoreceptors which respond more promptly, and that this effect occurs before the onset of secondary responses. The second aim of this study was to see if domperidone, a selective dopamine D_2 receptor antagonist which does not cross the blood–brain barrier,[13] could augment the response to this test in patients anaesthetized with isoflurane. We showed in a previous study[14] that domperidone offset the suppressive effect of isoflurane on HVR, presumably by antagonism of dopamine D_2 receptors in the carotid bodies.

Patients and methods

This double-blind, placebo-controlled study was approved by the local Research Ethics Committee. Written informed consent was obtained from 20 patients who were ASA I, not overweight and aged 18–65 yr. Patients were allocated randomly to receive either domperidone 20 mg or placebo tablets 1 h before arrival in the anaesthetic room.

In the anaesthetic room, an i.v. infusion was commenced and non-invasive monitoring of arterial pressure, ECG and pulse oximetry started. General

anaesthesia was induced with etomidate 0.3 mg kg^{-1} i.v. and anaesthesia was deepened with isoflurane and nitrous oxide in oxygen, with the patient breathing spontaneously. When anaesthesia was judged to be of adequate depth for tracheal intubation, laryngoscopy was performed and the larynx sprayed with a metered dose of a lignocaine preparation (Xylocaine, Astra Pharmaceuticals) using no more than 40 mg. After a short delay, the trachea was intubated and the inspired oxygen concentration was reduced to and maintained at 20% for the duration of the study. At the same time, the inspired isoflurane concentration was adjusted to obtain a stable end-tidal concentration of 0.4%, as measured by a Brüel and Kjaer gas monitor 1304, sampling at 90 ml min^{-1}, with a response time of less than 360 ms.[15] Headphones were placed on the patient's ears and white noise was played to prevent noise affecting breathing, and the arterial pressure cuff was not automatically inflated routinely in case it altered breathing pattern. Measurements of ventilatory variables during anaesthesia were started after a stable end-tidal isoflurane concentration had been present for at least 20 min.

The tracheal tube was connected via a screen pneumotachograph (F100L, Mercury Electronics) to an Ambu Hesse non-rebreathing valve. The pneumotachograph pressure signal was measured with a Furness FC044 differential pressure transducer (±10 mm H_2O). The inspiratory side of the valve was connected to a large bore two-way tap which allowed rapid changes between two supply systems. Anaesthetic gases (20% oxygen, isoflurane and nitrous oxide) were provided from a 4-litre reservoir bag fitted with a spill valve to reduce positive pressure in the supply tubing. Oxygen was supplied (flow rate of 6 litre min^{-1}) from a T-piece system using a 1-m length of anaesthetic tubing as a reservoir. The deadspace of the breathing system was approximately 80 ml.

Inspired and expired carbon dioxide and oxygen partial pressures and inspired and expired concentrations of isoflurane were measured continuously by the Brüel and Kjaer gas monitor. Gas monitor and flow signals were recorded on a lap-top computer using the commercial respiratory monitoring software Cardas (version 2.07 advanced, Oxcams, Oxford), running in MS-DOS (version 6.2) for later off-line analysis. The flow signal was integrated to obtain values for tidal volume (V_T) and instantaneous minute ventilation ($\dot{V}_E^{inst}$) calculated from tidal volume and respiratory cycle duration. Before each study, the pneumotachograph was calibrated against a 1-litre calibration syringe and the gas monitor was calibrated using a reference gas.

When clinically stable anaesthesia was achieved, the tap was turned during expiration so that two breaths of 100% oxygen were given. Tests were repeated at 2-min intervals. Five satisfactory two-breath oxygen tests were recorded. At the end of the testing sequence, a venous blood sample was obtained for measurement of plasma concentrations of domperidone and surgery started.

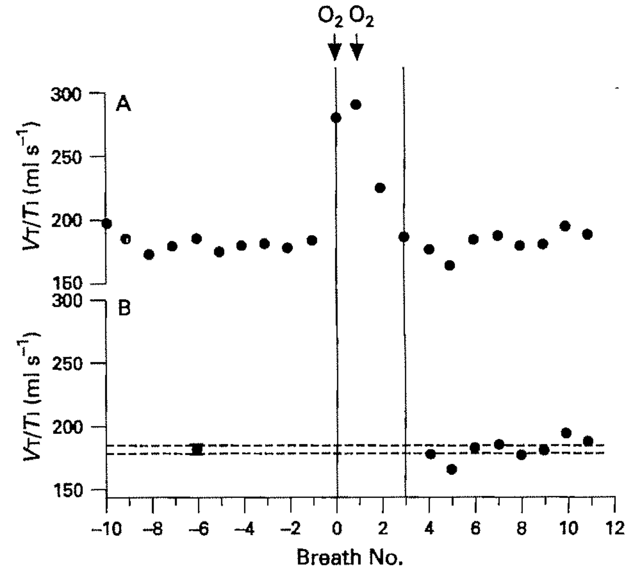

Figure 1 A: Mean inspiratory flow rate (V_T/T_I) from one patient showing the 10 breaths used as baseline and the post-test breaths analysed. The vertical lines indicate the two oxygen test breaths and the two breaths omitted from the analysis. B: Method used for analysis of transients. Baseline mean and 95% confidence limits (CL) used for testing against each post-test breath. Breaths below the horizontal dashed line are below the 95% CL of baseline and were considered definite responses (see text for further explanation)

ANALYSIS AND STATISTICS

We measured the 10 breaths before the two hyperoxic breaths as baseline. We ignored the two hyperoxic breaths (test breaths) and the following two breaths, as it required these additional breaths to elapse for exhaled oxygen to return to pre-test values. We then measured the eight subsequent breaths (fig. 1). Previous work has shown that maximum change in ventilation occurs after six breaths from the change in inspired oxygen.[11]

To reduce the influence of normal variation in breathing, the five hyperoxic tests for each patient were averaged on a breath-by-breath basis. We calculated means and 95% confidence limits (CL) for $\dot{V}_E^{inst}$ and mean inspiratory flow rate (V_T/T_I) for the 10 breaths used as baseline, and inspected the post-test breaths for a reduction to less than 95% CL of baseline. If any post-test breath was reduced below the 95% CL of baseline, this was considered a definite response provided that breaths increased again towards baseline after reaching a minimum value (fig. 1). From the V_T/T_I results, we recorded the post-test breath number with the smallest V_T/T_I. This breath was used subsequently for analysis of frequency, and inspiratory and expiratory time changes from baseline. The time from the hyperoxic stimulus to the breath with the smallest V_T/T_I was also noted.

To assess the reliability and consistency of this method of analysis, a random selection of five sets of 22 breaths was obtained in each patient during baseline breathing and subjected to the same averaging and analysis to assess if similar results could be obtained without the hyperoxic test breaths. Definite responses for both the placebo and domperidone groups were compared for any significant difference using the chi-square test with Yates' correction.

To assess if domperidone augmented the response to the hyperoxic test breaths, the mean maximal reductions in $\dot{V}_E^{inst}$ and V_T/T_I from baseline was calculated for both the placebo and domperidone groups. These values, and T_I and T_E changes from baseline, based on the minimum V_T/T_I post-test breath, were compared between groups using the Mann–Whitney test. Statistical significance was set at the 5% level.

Results

All patients completed the study without complications. The placebo and domperidone groups were comparable in age (mean 33 (range 26–53) and 34 (22–56) yr, respectively), weight (mean 73 (SD 15) and 72 (15) kg, respectively) and sex distribution (5M, 5F and 6M, 4F, respectively). Mean oxygen saturations were 92.7 (SD 2.3) % and 93.3 (1.9) %, respectively, and no patient had an oxygen saturation less than 90% when breathing an inspired oxygen concentration of 20%. Mean baseline end-tidal carbon dioxide partial pressures before the oxygen tests were 5.5 (range 4.5–6.0) kPa for the placebo group and 5.3 (4.2–6.3) kPa for the domperidone groups (ns).

After oxygen, all patients showed a transient reduction in $\dot{V}_E^{inst}$ and V_T/T_I with recovery towards baseline values by the end of the analysis period. $\dot{V}_E^{inst}$ and V_T/T_I analysis showed that the post-test breath with the maximum reduction occurred consistently within the same breath or two for each patient. In three patients, there were two consecutive transient reductions in $\dot{V}_E^{inst}$ and V_T/T_I and in these cases, the first transient was used for analysis.

Considering $\dot{V}_E^{inst}$, nine of 10 patients who received placebo and 10 of 10 patients who received domperidone demonstrated definite responses to the test. When the analysis was repeated for V_T/T_I, there were eight definite responses in the placebo group and 10 in the domperidone group. There was no significant difference in response frequency between groups. For both placebo and domperidone groups, mean times to minimum V_T/T_I after two hyperoxic breaths were 13.5 (SD 2.0) s and 14.9 (2.6) s, respectively. This corresponded to the minimum V_T/T_I breath occurring between breaths 5 and 11. This appeared to depend on the ventilatory frequency of the individual patient when the testing was performed, with higher ventilatory frequencies associated with a larger number of breaths to the minimum. Randomly selected sequences of breaths in each patient subjected to the same analysis did not show any transient reduction in minute ventilation with recovery towards baseline values.

Mean baseline $\dot{V}_E^{inst}$ and minimum minute ventilation after the test for each patient in each group are shown in table 1. The magnitude of the post-test reduction ranged from 0.04 to 0.53 litre min^{-1} of mean baseline ventilation in the placebo group and from 0.21 to 1.74 litre min^{-1} in the domperidone group. The overall mean reduction in ventilation was 0.30 litre min^{-1} for the placebo group and 0.55 litre min^{-1} for the domperidone group (table 2). These reductions differed significantly (P=0.05).

Mean baseline V_T/T_I and minimum V_T/T_I after the test for each patient in each group are shown in table 1. Changes in V_T/T_I after the test varied from an increase of 1 ml s^{-1} to a decrease of 27 ml s^{-1} compared with mean baseline values (placebo) and

Table 1 Mean (95% confidence limits) baseline $\dot{V}_E$, V_T/T_I, T_I and T_E, and post-test values after averaging of the five hyperoxic tests for each patient in the placebo and domperidone groups. Post-test $\dot{V}_E$ and V_T/T_I, are minimum values and *indicates definite response, that is outside the 95% confidence limit of baseline $\dot{V}_E$, and V_T/T_I, respectively. Post-test T_I and T_E, values were derived from the minimum post-test V_T/T_I, breath number

Table 2 Mean (range) baseline $\dot{V}_E$, V_T/T_I, T_I and T_E, and post-test values for the placebo and domperidone groups. Post-test $\dot{V}_E$ and V_T/T_I are minimum values and post-test T_I and T_E values were derived from the minimum post-test V_T/T_I breath number. Magnitude of change between baseline and post-test values are shown and *indicates significant difference ($P \leq 0.05$) from placebo

	Baseline	Minimum post-test	Δ Baseline— minimum post-test
$\dot{V}_E$ (litre min^{-1})			
Placebo	5.96 (4.72, 7.76)	5.65 (4.58, 7.34)	0.30 (0.04, 0.53)
Domperidone	6.67 (5.43, 8.66)	6.12 (5.12, 6.92)	0.55 (0.21, 1.74)*
V_T/T_I (ml s^{-1})			
Placebo	223 (183, 295)	215 (176, 288)	9 (−1, 27)
Domperidone	251 (188, 372)	224 (183, 296)	27 (6, 76)*
	Baseline	Post-test	Δ Baseline—post-test
T_I (s)			
Placebo	1 04 (0.89, 1.26)	1.07 (0.91, 1.23)	−0.04 (−0.13, 0.03)
Domperidone	1.08 (0.64, 1.39)	1.20 (0.65, 1.47)	−0.12 (−0.23, −0.01)*
T_E (s)			
Placebo	1.29 (0.94, 1.49)	1.35 (1.05, 1.59)	−0.06 (−0.18, 0.11)
Domperidone	1.31 (0.72, 1.84)	1.36 (0.74, 1.91)	−0.06 (−0.12, 0.02)

decreases from 6 to 76 ml s^{-1} (domperidone). The mean change was −9 ml s^{-1} for the placebo group and −27 ml s^{-1} for the domperidone group (table 2). These changes were statistically significantly ($P=0.02$).

Timing variables (T_I and T_E) for the minimum post-test V_T/T_I breath were compared with respective mean baseline values. With the exception of data from two patients in the placebo group, inspiratory times were lengthened after the test in both groups compared with baseline values (table 1). The mean increase in inspiration time for the placebo group was 0.04 s and 0.12 s for the domperidone group (table 2). There was a significant difference between groups ($P=0.02$). Expiration times were more variable but the trend was towards increasing expiration time in both groups (table 1). The mean increase for both groups was 0.06 s (table 2).

Mean plasma concentration of domperidone in the domperidone group was 7.9 (range 2.0–19.3) ng ml^{-1}. There was no correlation between plasma concentrations of domperidone and the size of the transient reductions in $\dot{V}_E^{inst}$ or V_T/T_I.

Discussion

We have shown that peripheral chemoreceptor activity was present in a majority of patients during isoflurane anaesthesia. Pre-existing stimulus to breathing was shown by transient depression of both $\dot{V}_E^{inst}$ and V_T/T_I after two breaths of 100% oxygen. With domperidone pretreatment, patients showed greater reductions in both $\dot{V}_E^{inst}$ and V_T/T_I after two breaths of 100% oxygen.

We reduced the respiratory depressant effects of other anaesthetic agents in this study by using etomidate for induction of anaesthesia, which has a short duration of action, and by avoiding the use of opioids. We averaged the repeated tests in each individual to reduce breath-to-breath variability so that small changes in ventilatory variables (as produced by this transient hyperoxia test) were more likely to be detected. Our method of testing for a definite response to hyperoxia is similar to that used in human studies involving single-breath carbon dioxide tests of peripheral chemosensitivity.[16] Randomly selected breaths subjected to the same analysis did not demonstrate the clear pattern of reduction followed by recovery towards baseline and we believe that this method of analysis reliably detected transient changes in responses. In our analysis, we ignored the two hyperoxic breaths (test breaths) and the following two breaths as there was a delay for the expired oxygen to return to baseline and we did not correct the pneumotachograph for changes in gas composition. As previous work showed that the maximum change occurred six breaths after the change in inspired oxygen,[11] we were unlikely to have missed the maximum change.

We used a variation of Dejours' test to assess the activity of the peripheral chemoreceptors during isoflurane anaesthesia. With this technique in resting awake humans, the magnitude of ventilatory change is approximately 8–10% of pre-stimulus baseline ventilation and occurs approximately 10 s after the stimulus.[17] In our study, during isoflurane anaesthesia, mean ventilatory change was 4.9% in the placebo group and 7.7% in the domperidone group and mean time to minimum V_T/T_I after stimulus was 13.5 s in the placebo group and 14.9 s in the domperidone group. This is longer than in awake subjects. Washin of oxygen to the alveoli and hence the change in arterial oxygen content may take longer during anaesthesia because ventilation is less in the anaesthetized subject. Alternatively, control of ventilation may be different from the awake state.

There are possible drawbacks of this test to assess chemoreceptor activity during anaesthesia. Hyperoxia can increase blood Pa_{CO_2} via the Haldane effect and thereby cause an increase in ventilation. Furthermore, hyperoxia can reduce cerebral blood flow which would tend to increase brain P_{CO_2} and thus also ventilation.[18] These effects, which are probably less rapid than effects at the peripheral chemoreceptors, would tend to oppose the decrease in ventilation caused by hyperoxia and therefore underestimate the magnitude of the ventilatory output of the peripheral chemoreceptors.

Duffin, Triscott and Whitwam[11] studied patients after opioid premedication and found that 0.7–0.8% halothane in air substantially decreased the ventilatory response to two breaths of oxygen compared with the response during thiopentone anaesthesia.

They concluded that halothane reduced the activity and responsiveness of peripheral chemoreceptors. As we did not have a group of patients in this study who did not receive isoflurane, we were unable to determine the effect of isoflurane anaesthesia *per se.* Our results only indicate that peripheral chemoreceptors appeared to be active during isoflurane anaesthesia. Different anaesthetic techniques such as the use of opioids and nitrous oxide and different ways of analysing the breaths may account for some of the differences observed. Furthermore, the anaesthetic concentrations used were different in the two studies; Duffin, Triscott and Whitwam[11] used approximately 1 MAC of halothane while we used approximately 0.3 MAC of isoflurane and 80% nitrous oxide. This difference could have influenced the degree of suppression of the peripheral chemoreceptors by these volatile agents. Nevertheless, it is likely that in our patients with an end-tidal isoflurane concentration of 0.4% (approximately 0.3 MAC), peripheral chemoreceptor activity was still present and responsive to changes in oxygen tensions, but perhaps not as vigorously as in awake subjects. Others have studied patients anaesthetized with 1.5% halothane, using a method derived from Dejours' test, and found that peripheral chemoreceptor activity was depressed but not abolished.[12]

Knill and coworkers[3] found that even at 0.1 MAC of isoflurane, there was a 50% reduction in the ventilatory response to isocapnic hypoxia. This was confirmed recently by van den Elsen and colleagues[10] who extended the concentration of isoflurane to 0.2 MAC and found a 65% reduction in isocapnic HVR. At anaesthetic concentrations of 1.1 MAC, HVR was virtually abolished.[3] This suggested that HVR and therefore the peripheral chemoreflex pathway was highly sensitive to the effects of isoflurane. However, our results and those of Clergue and co-workers[12] suggest that peripheral chemoreceptors are not "silent" at anaesthetic concentrations of isoflurane and halothane, respectively, suggesting that although peripheral chemoreceptor responses are depressed, this is perhaps not to the degree as suggested by previous investigators.[3] Our findings also support recent studies by Lindahl's group[4–6] who found persistent ventilatory responses to hypoxia under poikilocapnic conditions in patients anaesthetized with 0.6–0.85 MAC of isoflurane and a reduction of 60–70% in HVR under isocapnic conditions with 0.85–1.1 MAC of isoflurane. Therefore, anaesthetic concentrations of isoflurane do not appear to suppress HVR to the same extent as that found by previous investigators.[3 10] Differences in experimental conditions may account for some of these differences.[10]

Washin studies of subanaesthetic halothane and isoflurane[9 10] suggest that the most likely site of action of volatile agents is at the peripheral chemoreceptors. Depression of hypoxaemic-driven ventilation by halothane and isoflurane occurred extremely rapidly, within the first minute of inhalation. For isoflurane, it was estimated that after 30 s of isoflurane inhalation, the carotid body isoflurane tension would be approximately 90% of end-tidal, whereas the brain isoflurane tension would be approximately 8% of end-tidal.[10] Therefore, ventilatory depression occurring within 30 s of isoflurane inhalation is best explained by an action of isoflurane at the peripheral chemoreceptors. However, Whitwam and co-workers[19] demonstrated in anaesthetized patients that there was a mean delay of only 10 s in central chemoreceptor ventilatory response to i.v. injection of sodium bicarbonate (causing an increase in Pa_{CO_2}) when peripheral chemoreceptor activity was depressed by hyperoxia. This suggests that the time lag between the effect of isoflurane at central and peripheral chemoreceptor sites during washin could also be in the region of 10 s. Therefore, a central effect of subanaesthetic isoflurane cannot be excluded in the first 30 s of isoflurane washin and overall suppression of HVR at anaesthetic doses could be caused by a combination of peripheral and central effects.

The second aim of this study was to determine if domperidone, a selective dopamine D_2 receptor antagonist which does not readily cross the blood–brain barrier,[13] could augment the response to transient hyperoxia in patients anaesthetized with isoflurane. Domperidone augments HVR in humans[20] and can offset the suppression caused by isoflurane on the ventilatory response to hypoxia.[14] We found that with domperidone pretreatment, all patients showed positive results to transient hyperoxia suggesting that with increased ventilatory drive, it was easier to demonstrate the transient reductions in both $\dot{V}\mathrm{E}^{\mathrm{inst}}$ and $V\mathrm{T}/T\mathrm{I}$ after two breaths of 100% oxygen.

Analysis using $V\mathrm{T}/T\mathrm{I}$ instead of breath-by-breath minute ventilation demonstrated a greater difference between placebo and domperidone. $V\mathrm{T}/T\mathrm{I}$ is a measure of respiratory drive allowing minute ventilation to be separated into drive and timing components: $\dot{V}\mathrm{E}^{\mathrm{inst}}$ is the product of $V\mathrm{T}/T\mathrm{I}$ and $T\mathrm{I}/T\mathrm{TOT}$ (timing component where $T\mathrm{TOT}$ is the sum of $T\mathrm{I}$ and $T\mathrm{E}$).[21] When inspiratory and expiratory times were compared between groups, only $T\mathrm{I}$ was significantly different, with domperidone causing an increase in inspiration time. These results support the observations of Clergue and co-workers who found a prompt change in $T\mathrm{I}$ after oxygen breathing commenced.[12]

In summary, our data support the view that peripheral chemoreceptors remain active during isoflurane anaesthesia. Their function may be depressed by isoflurane, but perhaps not as much as suggested previously. Domperidone enhanced peripheral chemosensor activity by increasing respiratory drive during isoflurane anaesthesia.

Accuracy and clinical performance of a continuous intra-arterial blood-gas monitoring system during thoracoscopic surgery†

A. Zollinger, D. R. Spahn, T. Singer, M. P. Zalunardo, S. Stoehr, W. Weder and T. Pasch

Summary

Accuracy and performance of the only currently available intra-arterial blood-gas monitoring system (Paratrend 7, PT7) were assessed in 23 patients during thoracoscopic surgery using one-lung ventilation. Over a wide range of values for arterial P_{O_2} (6.1–61.1 kPa), P_{CO_2} (4.1–9.5 kPa) and pH (7.19–7.50), 138 arterial blood-gas values obtained by PT7 were compared with corresponding *in vitro* laboratory blood-gas measurements. We found good clinical performance with the PT7 and good agreement between PT7 values and *in vitro* measurements for arterial P_{O_2} (bias (1.96 SD)=0.38 (9.52) kPa), P_{CO_2} (0.31 (0.76) kPa) and pH (−0.017 (0.065)). Also, the bias for sequential changes between two consecutive times was not significantly different from the ideal value of 0. We conclude that the PT7 is helpful in monitoring patients during thoracoscopy. (*Br. J. Anaesth.* 1997; **79**: 47–52).

Key words
Measurement techniques, gas exchange. Equipment, blood-gas monitors. Surgery, thoracic. Ventilation, one-lung.

Video-assisted thoracoscopic surgery is used widely for an increasing number of diagnostic and therapeutic procedures in patients with compromised lung function. Additionally, one-lung ventilation (OLV) is necessary to provide a collapsed lung on the side of operation, and this is often associated with significant changes in arterial blood-gas tensions. Oxygenation may be impaired by significant intrapulmonary shunting, and carbon dioxide removal may be impaired by increased deadspace ventilation. Furthermore, lateral positioning of patients is usually necessary for an optimal surgical approach and may contribute further to ventilation–perfusion mismatch resulting in compromised gas exchange. In order to prevent hypoxaemia and hypercapnia, repeated *in vitro* (laboratory) blood-gas analyses are performed frequently during OLV to control and adjust ventilation and oxygenation of the lungs. Continuous intra-arterial blood-gas monitoring would be advantageous because changes in oxygenation and carbon dioxide elimination can be recognized and treated immediately.[1]

The Paratrend 7 (Biomedical Sensors Ltd, Pfizer Hospital Products Group, High Wycombe, UK) is a fast-response intra-arterial blood-gas monitoring system which may be suitable for detection of rapid changes in arterial P_{O_2}, P_{CO_2} and pH values during thoracic surgery with OLV. It is currently the only commercially available intravascular blood-gas sensor system. The Paratrend 7 system (PT7), however, has been validated by only one group of authors in an experimental animal study[2] and, for limited P_{O_2}, P_{CO_2} and pH ranges, in the intensive care unit and during cardiac surgery.[3–5]

This study was performed to evaluate prospectively the clinical accuracy and performance of the Paratrend 7 intra-arterial blood-gas monitoring system during thoracoscopy over a wide range of PO_2, P_{CO_2} and pH values.

Patients and methods

Twenty-three patients undergoing elective thoracoscopic surgery gave their written informed consent to participate in this study, which was approved by the local Ethics Committee.

INTRAVASCULAR BLOOD-GAS SENSOR

The Paratrend 7 (PT7) is a multi-parameter sensor system incorporating four different sensors: P_{O_2} is measured by a miniaturized Clark electrode, P_{CO_2} and pH are measured by Optodes, and blood temperature is determined by a thermocouple. The four sensor elements are housed in a heparin-coated microporous polyethylene tubing of approximately 0.5 mm in diameter, suitable for insertion through a 20-gauge or larger size catheter. The tip with the sensor elements, approximately 4 cm in length, has to float freely in the arterial lumen. The device with the blood-gas sensor incorporates a tubing system enabling simultaneous continuous intravascular arterial pressure measurement and intermittent

blood aspiration via a sideport for repeated *in vitro* laboratory blood-gas measurement. The disposable sensor is sealed by the manufacturer within a tonometer containing buffer solution, which maintains hydration and serves as a calibration medium. Before insertion into the patient, the sensor is calibrated under microprocessor control by the PT7 monitor using three precision gases bubbled through the tonometer. The calibration procedure takes 30 min. According to the manufacturer's guidelines, the sensor should be inserted into the artery within 8 h thereafter. Later, re-calibration of the system using the values of *in vitro* laboratory blood-gas determinations as a reference is only recommended every 12 h. After insertion of the calibrated sensor, the PT7 monitor provides continuous graphical and numerical display of the measured values $P\text{o}_2$, $P\text{co}_2$, and pH. Temperature and calculated values $S\text{o}_2$, HCO_3- and BE are displayed numerically.

Patients received oral premedication with midazolam 3.75–7.5 mg, 30–45 min before transfer to the operating theatre. After insertion of an 18-gauge i.v. cannula (Adsyte, Becton Dickinson Vascular Access Inc., UT, USA), a radial artery (left/right=16/7) was cannulated under local anaesthesia using a 5.1 cm long, 20-gauge catheter (Insyte, Becton Dickinson Vascular Access Inc., Sandy, UT, USA). A pressure transducer (Uniflow 43–600F, Baxter, Bentley Laboratories Europe, Uden, The Netherlands) was connected to the sideport of the previously calibrated PT7 sensor system for continuous intra-arterial pressure measurement. The pressure transducing tubes were prefilled with a solution of normal saline containing heparin 2 u. ml^{-1}. While flushing continuously from a pressurized flush bag, the sensor was inserted through the radial cannula, advanced to a depth of 15 cm and attached to the skin with adhesive tape. Any movements of the hand were prevented to avoid kinking of the PT7 sensor. The arterial pressure waveform was displayed on a Hellige monitor (VICOM-SM SMU 612, PPG Hellige, Freiburg, Germany) and the continuous intra-arterial blood-gas measurements displayed on the PT7 monitor. Additional routine monitoring of patients consisted of five-lead ECG, pulse oximetry, rectal temperature measurement and measurements of end-tidal concentrations of carbon dioxide and inhalation anaesthetics (all VICOM-SM SMU 612, PPG Hellige, Freiburg, Germany). Anaesthesia was induced using thiopentone and fentanyl i.v. Neuromuscular block was produced with suxamethonium. Left endobronchial intubation was performed with a double-lumen tube (Sher-I-Bronch, Sheridan Catheter Corp., Argyle, NY, USA) under fibreoptic control. Enflurane in oxygen and air, fentanyl and pancuronium were used for maintenance of anaesthesia and neuromuscular block. Volume-controlled ventilation was used (Siemens Servo 900 D ventilator, Siemens Life Support Systems, Solna, Sweden), and ventilatory patterns were adjusted by an experienced anaesthetist tailored to the individual patient. Positioning of patients was performed according to surgical needs (left lateral 14 patients; right lateral eight patients; supine one patient). To provide a collapsed lung on the side of operation, OLV with an inspired oxygen fraction of 1.0 was induced on the contralateral side before skin incision for introduction of the trocar through the seventh or eighth intercostal space, and maintained throughout thoracoscopy. At the end of surgery a drainage tube was inserted and the collapsed lung was again ventilated.

DATA COLLECTION

The PT7 sensor was inserted immediately after the initial calibration procedure was completed in all cases, and was not re-calibrated thereafter. Data were obtained after induction of anaesthesia, 5, 10, and 20 min after the onset of OLV, before the end of OLV, and 10 min after two-lung ventilation was re-established. Provided that system stability was indicated by the PT7 computer according to the manufacturer's manual, arterial blood-gas values displayed on the PT7 monitor were stored at these times. Simultaneously, a 1-ml blood sample was obtained for *in vitro* blood-gas analysis from the radial artery cannula using a pre-heparinized syringe (QS 50, Radiometer Medicals, Copenhagen, Denmark). *In vitro* measurement was performed within the next 2 min (IL 1400 BGE-analyzer with IL 482 co-oximeter, Instrumentation Laboratory, Milano, Italy) by a laboratory technician who was unaware of the *in vivo* PT7 values. Both PT7 and blood-gas analysis values were determined at 37 °C and thus no temperature correction was performed. Rectal and PT7 temperature readings were also recorded.

DATA ANALYSIS

All results were analysed using StatView 4.1 software (Abacus Concepts, Inc., Berkeley, CA) on an Apple Macintosh computer. Data are presented as mean (SD). Bias (mean of the differences PT7 − blood-gas analysis (BGA)) and precision (1.96 SD of these differences) were calculated[6] for arterial pH, $P\text{o}_2$, $P\text{co}_2$, $S\text{o}_2$, HCO_3-, BE and temperature. Simple linear regression analyses were performed for arterial $P\text{o}_2$, $P\text{co}_2$, SO_2, HCO_3-, BE and temperature, but not for pH because of its logarithmic scale. The pH values, instead, were converted to $[H^+]$, and linear regression analysis and calculation of bias and precision were performed. Furthermore, sequential changes in arterial PO_2, $P\text{co}_2$, pH and $[H^+]$ between two consecutive times (delta $P\text{o}_2$ delta $P\text{co}_2$, delta pH, delta $[H^+]$) were calculated for PT7 and BGA. Bias and precision of these changes were calculated for delta $P\text{o}_2$ delta $P\text{co}_2$, delta pH and delta $[H^+]$, and linear regression analyses were performed for delta $P\text{o}_2$, delta $P\text{co}_2$ and delta $[H^+]$. One-sample Sign tests were used to compare biases with the hypothesized ideal value of 0. $P<0.05$ was considered statistically significant.

Results

All 23 patients were studied (mean age 55 (range 20–76) yr; male/female ratio 17/6; ASA grade I, two patients, grade II, 12 patients, grade III, eight

Table 1 Arterial blood-gas values obtained by the Paratrend 7 monitor (PT7) and by simultaneous *in vitro* blood-gas analysis (BGA). Arterial $P\mathrm{O}_2$, $P\mathrm{CO}_2$ and pH were measured by both systems, HCO_3- and BE were calculated by both systems. $S\mathrm{O}_2$ was measured by the co-oximeter and calculated by the Paratrend 7. $n=138$

patients, grade IV, one patient). The operations performed were: lung resection (14), pleurectomy (six), bullectomy (two) and sympathectomy (one). Duration of anaesthesia was 220 (68) min, duration of operation was 106 (61) min and duration of OLV was 99 (58) min. All PT7 sensors calibrated and inserted into a radial artery measured intra-arterial blood-gas tensions throughout the study and there were no technical failures. According to the study design, six measurements in 23 patients were performed, producing 138 PT7 readings with corresponding blood-gas analysis values. Positioning of patients and diathermy did not affect sensor function. No complications attributable to the sensor were observed.

On average, near normal arterial $P\mathrm{CO}_2$ and high $P\mathrm{O}_2$ values were found (table 1). However, extreme blood-gas values were observed during thoracoscopic surgery and OLV, which offered the opportunity to study the accuracy of the PT7 over a wide range of blood-gas analysis values (table 1). PT7-$P\mathrm{O}_2$ corresponded very well with BGA-$P\mathrm{O}_2$, as evidenced by non-significant bias (0.38 kPa) and a correlation coefficient of 0.95 (table 2, fig. 1). Also, PT7-$P\mathrm{CO}_2$ corresponded well with BGA-$P\mathrm{CO}_2$, as documented by a bias of 0.31 kPa ($P<0.0001$) and a correlation

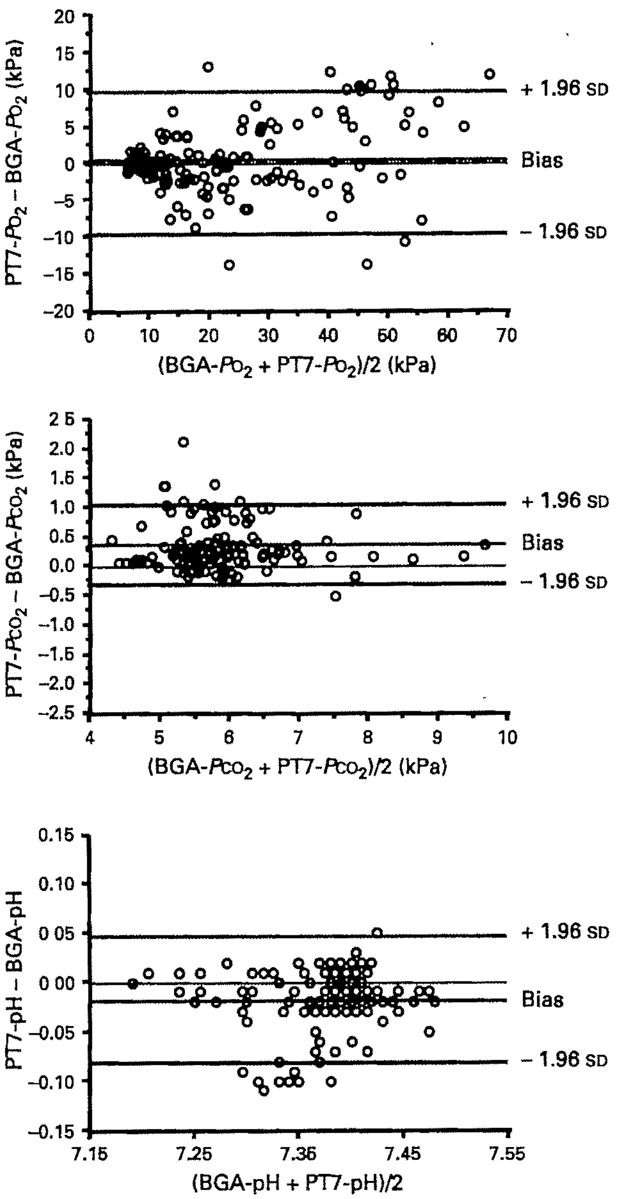

Figure 1 Bland Altman plots[6] showing bias (mean of differences) and precision (1.96 SD of these differences) *vs* mean values of arterial $P\mathrm{o}_2$, $P\mathrm{co}_2$ and pH obtained by Paratrend 7 (PT7) compared with values obtained by *in vitro* blood-gas measurement using a co-oximeter (BGA). $n=138$.

coefficient of 0.90 (table 2, fig. 1). Furthermore, the calculated $[\mathrm{H}^+]$ concentrations derived from the PT7-pH values correlated well with those derived from BGA-pH (correlation coefficient 0.84) (table 2). Bias between PT7-pH and BGA-pH was relatively small (-0.017; $P<0.0001$) (table 2, fig. 1). However, agreement of the calculated values $\mathrm{HCO_3^-}$ (0.43) and BE (0.56) was relatively poor (table 2). Mean PT7 radial temperature values were lower than those recorded rectally (table 3). The bias of the sequential changes between two consecutive times (delta $P\mathrm{o}_2$, delta $P\mathrm{co}_2$, delta pH, delta $[\mathrm{H}^+]$) was not significantly different from the hypothesized ideal value of 0 (table 4), and a good correlation coefficient between BGA and PT7 was found for the values delta $P\mathrm{o}_2$ (0.97), delta $P\mathrm{co}_2$ (0.87) and delta $[\mathrm{H}^+]$ (0.87) (table 4, fig. 2).

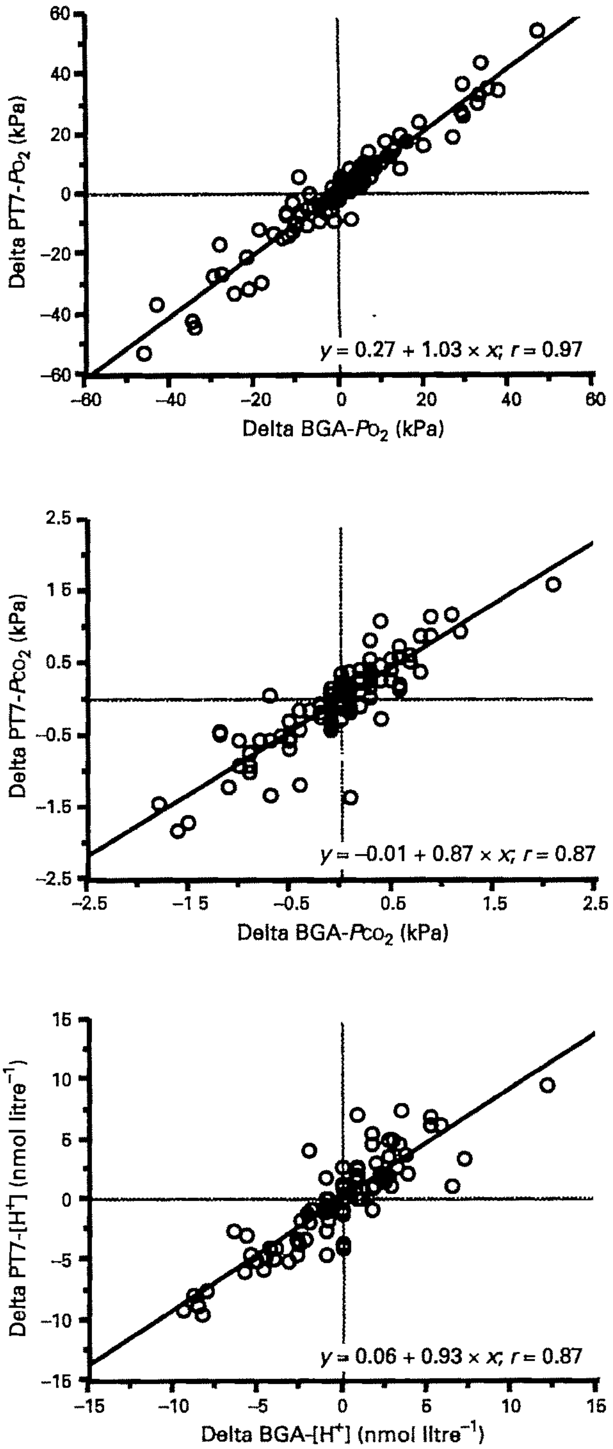

Figure 2 Linear regression analysis plots showing sequential changes in arterial $P\mathrm{o}_2$, $P\mathrm{co}_2$ and $[\mathrm{H}^+]$ between two consecutive times (delta $P\mathrm{o}_2$, delta $P\mathrm{co}_2$, delta $[\mathrm{H}^+]$) obtained by Paratrend 7 (PT7) *vs* corresponding changes obtained by *in vitro* blood-gas measurement using a co-oximeter (BGA). $n=115$.

Discussion

The results of this study indicate good clinical performance of the Paratrend 7 multi-parameter sensor. In all patients the sensor was inserted into the radial artery catheter without difficulties and accurately measured arterial blood-gas tensions continuously during thoracoscopy over a wide range of $P\mathrm{o}_2$, $P\mathrm{co}_2$ and pH values (see tables 1 and 2; fig. 1).

The correlation of So_2 values calculated by the PT7 compared with *in vitro* values determined by the co-oximeter was also satisfactory (table 2). However, radial PT7 temperature compared with rectal temperature (table 3), and values of HCO_3- and BE calculated by and displayed on the Paratrend 7 monitor showed poor correlation with those calculated from the *in vitro* blood-gas determinations (table 2).

Thoracoscopy necessitates OLV with close monitoring of arterial blood-gas tensions. Intermittent blood-gas measurement is currently standard care and insertion of an intra-arterial catheter is usually required. Although this represents a "continuously invasive" method, blood-gas determination is still only intermittent. Recently, serious shortcomings of conventional intermittent blood-gas analyses have been discussed.[7–10] The most obvious disadvantage is the dependence on clinical judgement as to when blood samples should be obtained. Adequate and immediate detection of serious events by the anaesthetist is presumed, blood has to be sampled in time and the results should be available rapidly. In many critical situations, however, blood sampling, transport and laboratory analysis is only possible with a considerable delay, and sampling rate is inherently limited. Thus intermittent blood-gas measurement represents a "snapshot" of a continuous physiological variable and is frequently obtained after a critical event has already occurred.[7] Continuous intra-arterial blood-gas monitoring, on the other hand, provides relevant physiological information on-line, including display of trends of measured variables. Furthermore, alarm limits for the variables may be defined. Continuous intra-arterial blood-gas monitoring is therefore desirable, provided that such a system is accurate.

Several clinical studies on the performance of intravascular sensor systems have been published[3–5 9–16] and the results have been reviewed recently.[17 18] None of these systems, however, is available commercially, except for the PT7. Unfortunately, the PT7 system has been validated clinically by only one team of investigators in collaboration with the manufacturer.[3–5] Assessing accuracy and clinical performance of the PT7 system independently is therefore important. In thoracoscopy, using OLV, we had the opportunity to assess the accuracy of the PT7 system over a wide range of arterial Po_2 (6.1–61.1 kPa), Pco_2 (4.1–9.5 kPa) and pH (7.19–7.50) values. We found good agreement of PT7 values and *in vitro* blood-gas analysis values for arterial Po_2, Pco_2 and pH (fig. 1, table 2). This is in keeping with previous studies in intensive care medicine[3] and cardiac surgery.[4 5] Furthermore, comparison of sequential changes between two consecutive times (delta Po_2, delta Pco_2, delta pH) showed good agreement (table 4, fig. 2), and no clinically relevant changes in PT7 values compared with changes in blood-gas analysis values were observed. This is of the utmost importance for a continuous monitoring system, as it is designed primarily to accurately reflect trends in measured variables.

Radial PT7 temperature was significantly lower than rectal temperature (table 3). This is not surprising as the radial artery may be considered an intermediate or even a peripheral temperature measuring site: core temperature is reflected more accurately by rectal rather than axillary temperature measurements during anaesthesia.[19] Therefore, both PT7 and blood-gas analysis values were determined at 37 °C in this methodological study. The PT7 system, however, offers the choice between measurement of blood-gas tensions at 37 °C (as performed in this investigation) and at patient (intravascular) temperature. Comparison of the two methods was not the object of this study.

Comparing PT7 and laboratory blood-gas analysis results is difficult because laboratory blood-gas analysis measurement is fraught with a variety of problems: samples for blood-gas analysis may easily be handled incorrectly by sample dilution, excess heparinized saline,[20 21] delays in analysis with the sample being stored at room temperature,[20 22] oxygen consumption from metabolism by leucocytes and other cells contained in the sample,[23] diffusion of gases through the plastic wall of syringes[24–26] and pressure of air bubbles in the samples,[22 26 27] particularly during transport.[28] In addition, the accuracy and variability of laboratory blood-gas analysers are not known exactly. The following criteria were applied in a recent evaluation of blood-gas analysers[29]: in the Po_2 range of 4–20 kPa and Pco_2 range of 2.7–10.6 kPa, respectively, 95% of measurements should be within $\pm 7.5\%$ or ± 0.6 kPa of a reference; for $Po_2 > 20$ kPa and $Pco_2 > 10.6$ kPa, respectively, 95% of measurements should be within $\pm 12.5\%$ of a reference; pH accuracy cannot be tested because there is no reference method.[29] Differences between PT7 and laboratory blood-gas values thus cannot *a priori* be considered to represent variability in the new method, that is the PT7, but may also result from errors in laboratory blood-gas analysis or in both of these methods.

The observed variability of PT7 Po_2, Pco_2 and pH measurements is acceptable for clinical decision making, and PT7 is a reliable trend indicator of arterial blood-gas tensions. During thoracoscopy with OLV, in selected cases, continuous intra-arterial blood-gas monitoring is therefore helpful in monitoring oxygenation and carbon dioxide. However, cost effectiveness and influence on outcome of this particular technology must be examined.[30 31] Whether the good clinical performance will translate into improved long-term outcome has not yet been investigated and requires further study.[32–34]

In summary, we found good accuracy and good clinical performance of the Paratrend 7 sensor system when used in patients during thoracoscopy. It appears to be a helpful tool in monitoring patients during surgical procedures associated with large variations in arterial blood-gas tensions, such as thoracoscopy with OLV.

Midlatency auditory evoked potentials and motor signs of wakefulness during anaesthesia with midazolam

D. SCHWENDER, M. DAUNDERER, N. SCHNATMANN, S. KLASING, U. FINSTERER AND K. PETER

Summary

We have studied midlatency auditory evoked potentials (MLAEP) and motor signs of wakefulness during anaesthesia with midazolam in 10 patients undergoing elective laparotomy under continuous extradural analgesia. Anaesthesia was induced with midazolam 0.3 mg kg^{-1} and maintained with midazolam 0.3–0.9 mg kg^{-1} h^{-1}. Motor signs of wakefulness were documented as spontaneous movements and movements after simple commands (open eyes or move arms). MLAEP were recorded continuously awake, and during anaesthesia until the end of anaesthesia. Latencies of the peaks V, Na, Pa, Nb and P1 (ms) and amplitudes of the peaks Na/Pa, Pa/Nb and Nb/P1 (μV) were measured. Twenty-five movements were observed during anaesthesia; 15 movements in six patients were in response to commands. In two patients supplementary isoflurane was given. Latencies of the MLAEP peaks Pa, Nb and P1 increased slightly during anaesthesia. Amplitudes for Na/Pa, Pa/Nb and Nb/P1 did not change significantly. The high incidence of motor signs of wakefulness associated with preserved MLAEP indicated a high level of cortical neural activity and none of the MLAEP variables predicted movement during anaesthesia with midazolam. (*Br. J. Anaesth.* 1997; **79**: 53–58).

Key words
Hypnotics benzodiazepine, midazolam. Anaesthetics volatile, isoflurane. Monitoring, evoked potentials. Brain, evoked potentials.

The early auditory evoked potentials (AEP), generated in the brainstem, change only slightly during anaesthesia with volatile agents.[1–3] The late cortical components show great variation in latency and amplitude in the awake state and are not present during anaesthesia.[4 5] In contrast, midlatency peaks of the AEP do not differ appreciably either between individuals or over time. However, a range of anaesthetic agents depress midlatency auditory evoked potentials (MLAEP) in a dose-dependent manner.[1 2] Therefore, it has been suggested that MLAEP may be used to measure depth of anaesthesia and to indicate intraoperative awareness.[6 7] During induction of general anaesthesia with benzodiazepines, MLAEP appeared to be preserved compared with the awake state.[8] This observation may be relevant to occasional reports on intraoperative awareness during anaesthesia with benzodiazepines. In this study, we recorded MLAEP and motor signs of wakefulness continuously online while patients were awake and during anaesthesia with midazolam.

Patients and methods

After obtaining Institutional Ethics Committee approval and informed consent, we studied 10 patients, aged 20–60 yr, ASA I and II, undergoing elective laparotomy. After oral premedication with a benzodiazepine (clorazepate 20 mg), 45–60 min before anaesthesia, electrocardiograph electrodes (ECG) and an i.v. catheter were placed, and continuous extradural block was performed at L3–4 or L4–5. Using 0.5% bupivacaine the level of anaesthesia was maintained at T4–5. General anaesthesia was induced with midazolam 0.3 mg kg^{-1} i.v. After induction of anaesthesia and loss of consciousness (no response to verbal commands, loss of eyelid reflex) patient's lungs were ventilated with 100% oxygen via a face mask. Suxamethonium 1.0–1.5 mg kg^{-1} was given for neuromuscular block, the trachea intubated and controlled ventilation with 50% nitrous oxide in oxygen was commenced. No other neuromuscular blocking agents were used. To maintain general anaesthesia, patients received midazolam 0.3 mg kg^{-1} h^{-1} i.v. Heart rate (via a three-lead ECG), systemic arterial pressure (via an arterial cannula in the radial artery) and central venous pressure (via a catheter in the internal jugular vein) were recorded continuously. Mean arterial pressure was maintained at greater than 70 mm Hg. Body core temperature was measured by an oesophageal temperature probe and maintained at more than 35.5 °C using heated blankets and warmed infusions. Controlled ventilation was

adjusted to maintain normocapnia (end-expiratory $P\text{CO}_2$ 4.7–5.3 kPa) and verified by intermittent arterial blood-gas analysis. Doses of anaesthetics were guided by clinical signs of adequate anaesthesia (i.e. changes in arterial pressure, heart rate, sweating and tear production). Light anaesthesia was indicated by changes in the "pressure rate, sweating and tears" (PRST) score from baseline[9]. A PRST score greater than 2 or spontaneous movements of the patients were defined as indicative of light anaesthesia. Spontaneous movements of the head and arms, eye-opening or other facial movements were documented. Intermittently (every 10 min) patients were asked to follow simple commands (open eyes or move arms). If light anaesthesia was present, the infusion rate of midazolam was increased by 0.3 mg kg^{-1} h^{-1} up to 0.9 mg kg^{-1} h^{-1} i.v. When patients continued to show signs of light anaesthesia 10 min after the increase in midazolam infusion rate to 0.9 mg kg^{-1} h^{-1} i.v., anaesthesia was supplemented with 0.4–1.0 vol% isoflurane end-expiratory concentration. To evaluate conscious recall of anaesthesia and surgery, patients were asked at an informal postoperative interview to remember explicitly anything they may have perceived during anaesthesia.

The electrodiagnostic system Pathfinder I (Nicolet Instrument Corporation, Madison, WI, USA) was used for auditory stimulation, recording and analysis of evoked potentials. Rarefaction clicks of 0.1 ms duration and 70 dB greater than mean auditory threshold were presented binaurally with a stimulation frequency of 9.3 Hz using acoustically shielded earphones (TDH 39, Amplivox, Manchester, UK). For recording, silver electrodes were positioned at Cz and A_1/A_2 with Fpz as ground (according to the international 10–20 system). Impedance of all electrodes was maintained at less than 3 kΩ. Input signals were sampled at 5120 Hz during 100-ms post-stimulus epochs and averaged across 1000 stimulus presentations and digitally bandpass filtered (10–500 Hz). The recording procedure was controlled visually on a monitor, and an automatic artefact rejection procedure rejected signals greater than 96% of full scale. Line frequency suppression was set at 50 Hz. To guarantee correct transmission and transduction of the auditory stimuli, evoked potentials without a brainstem response (peak V) were rejected. Latencies of the peaks V, Na, Pa, Nb and P1 (ms) and amplitudes of Na/Pa, Pa/Nb and Nb/P1 (μV) were measured. For each observation, AEP of individual patients and a grand average calculated from individual AEP of all patients were generated. AEP were recorded continuously on-line while awake and during induction and maintenance of general anaesthesia, until the end of anaesthesia when patients' tracheas were extubated and they had recovered from anaesthesia. One AEP generated from 1000 responses with a stimulation rate of 9.3 represented approximately a 2-min period.

Results are presented as mean (SD). Cardiorespiratory variables and spontaneous movements were correlated by a time series analysis. For the peak latencies V, Na, Pa, Nb and P1 and amplitudes Na/Pa, Pa/Nb and Nb/P1, the Wilcoxon test was used. Statistical significance was assumed if $P<0.05$ after Bonferroni's correction for multiple comparisons.

Results

Patient characteristics, type and dose of premedication, type of surgery, total duration of surgery and anaesthesia, and total dose of bupivacaine given are presented in table 1. There were no significant changes in systolic and diastolic arterial pressures (SAP, DAP) or heart rate (HR) while awake, after induction or during maintenance of anaesthesia, or

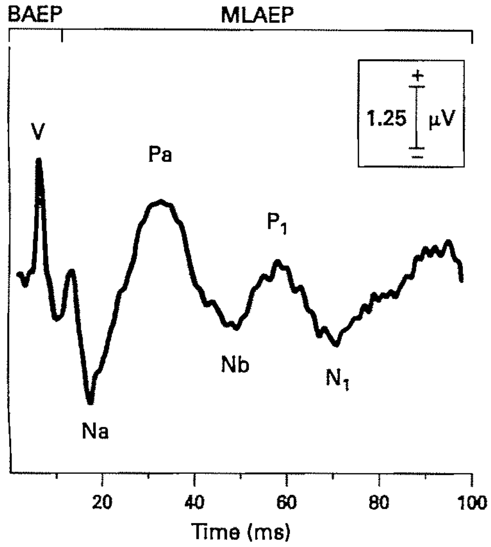

Figure 1 Auditory evoked potential of an awake patient. BAEP=Brainstem auditory evoked potential, MLAEP=midlatency auditory evoked potential.

during emergence from general anaesthesia (see table 2). We observed 25 movements (11 movements of the arm, 14 eye openings) during anaesthesia; 15 movements in six patients were in response to commands. One patient moved twice, two patients moved three times and two patients moved four times during anaesthesia. One patient had explicit recall of intraoperative events at the postoperative interview. In six patients the infusion rate of midazolam was increased and in two patients supplementary isoflurane was given. The trachea of all patients was extubated and patients regained consciousness at the end of anaesthesia. There were no correlations between haemodynamic data and movements observed during operation.

Figure 1 shows an original tracing of an AEP of an awake patient. Wave V is part of the brainstem generated potentials (BAEP); the MLAEP peaks Na, Pa, Nb, P1 show high amplitudes and a characteristic periodic waveform.

Figures 2 and 3 show typical original recordings of AEP of two individual patients while awake, during maintenance of anaesthesia (no movement) (figs 2A, 3A), during anaesthesia 8, 6, 4 and 2 min before and during intraoperative movement (figs 2B, 3B) and during emergence from anaesthesia (figs 2C, 3C). MLAEP of the awake patients had large amplitudes and a periodic waveform. During anaesthesia (no movements detected) latencies of the MLAEP peaks Nb and P1 increased only slightly with amplitudes of Na/Pa, Pa/Nb and Nb/P1 of MLAEP preserved (figs 2A, 3A). Before and during intraoperative movement, MLAEP did not change significantly compared with the preceding recordings during anaesthesia when no movements were seen. Nb and P1 were increased slightly compared with the awake state, and amplitudes Na/Pa, Pa/Nb and NB/P1 did not change significantly and were the same as those recorded in the awake state (figs 2B, 3B). The same pattern of MLAEP behaviour was observed during emergence from general anaesthesia (figs 2C, 3C).

Figure 4 shows the grand averages of the individual auditory evoked potentials awake, during anaesthesia with no movement observed (fig. 4A), during anaesthesia 8, 6, 4 and 2 min before and during intraoperative movements (fig. 4B), and during emergence from general anaesthesia (fig. 4C). MLAEP of the awake patients showed large peak-to-peak amplitudes and a periodic waveform. During anaesthesia with no movements observed, there was a slight increase in MLAEP latencies. MLAEP amplitudes were preserved (fig. 4A) before and during intraoperative movements. MLAEP did not

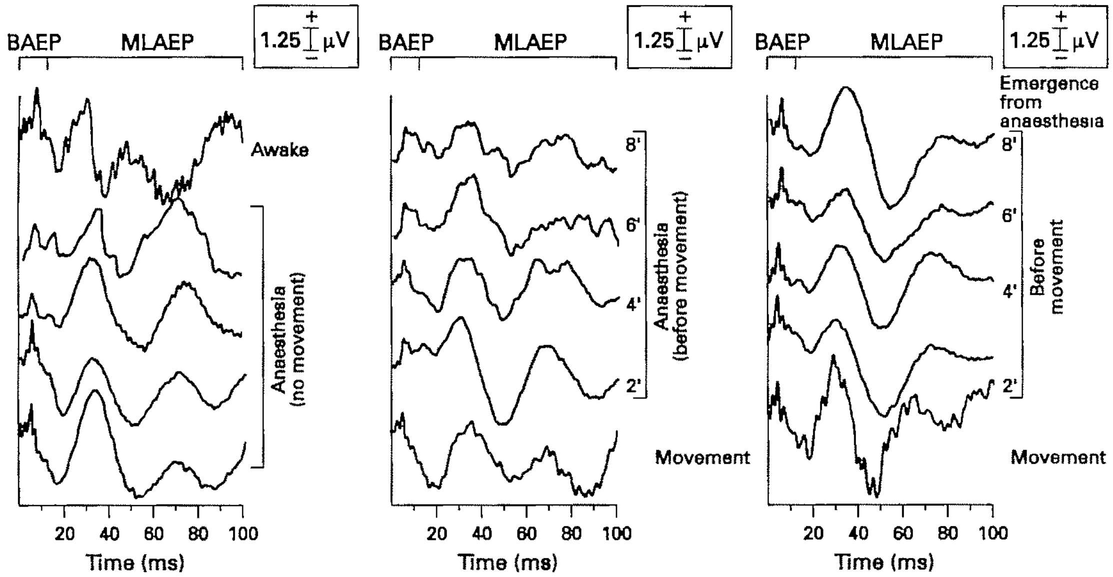

Figure 2 Auditory evoked potentials of an individual patient while awake, during anaesthesia with no movement observed (A), during anaesthesia 8, 6, 4 and 2 min before and during intraoperative movements (B), and during emergence from general anaesthesia (C). BAEP=Brainstem auditory evoked potential, MLAEP=midlatency auditory evoked potential. MLAEP of the awake patient had large amplitudes and a periodic waveform. During maintenance of anaesthesia MLAEP increased only slightly in latencies with amplitudes preserved. Before and during patient movements, observed during operation or during emergence from anaesthesia, amplitudes of the MLAEP were the same as those recorded while awake.

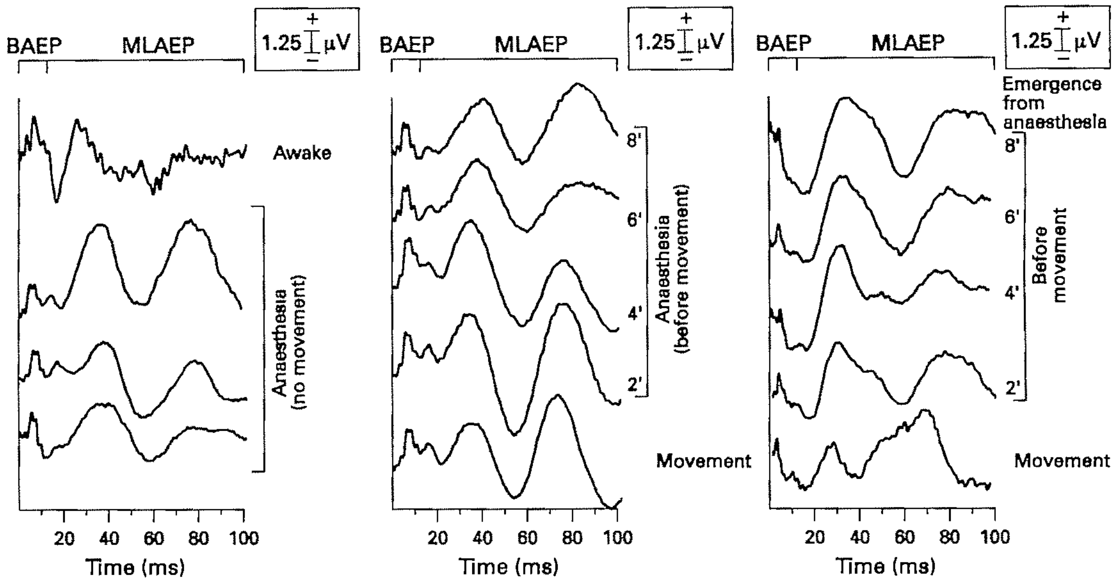

Figure 3 Auditory evoked potentials of a second individual patient while awake, during anaesthesia with no movement observed (A), during anaesthesia 8, 6, 4 and 2 min before and during intraoperative movements (B), and during emergence from general anaesthesia (C). Abbreviations and features as in figure 2.

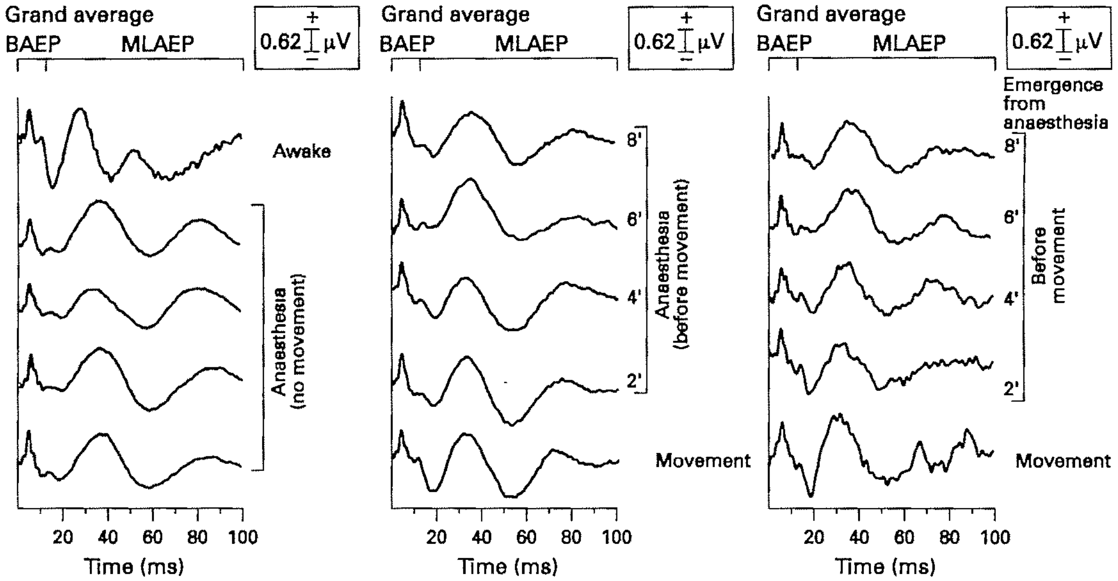

Figure 4 Grand averages of individual auditory evoked potentials while awake, during anaesthesia with no movement observed (A), during anaesthesia 8, 6, 4 and 2 min before and during intraoperative movements (B), and during emergence from general anaesthesia (C). BAEP=Brainstem auditory evoked potential, MLAEP=midlatency auditory evoked potential. Anaesthesia did not lead to significant suppression of MLAEP. When movements were observed, MLAEP showed a similar pattern as in the awake state before operation.

change compared with the preceding recordings during anaesthesia and were the same as in the awake state (fig. 4B). The same pattern was observed during emergence from anaesthesia (fig. 4C).

Mean values of the latencies of V, Na, Pa, Nb and P1 and amplitudes of Na/Pa, Pa/Nb and Nb/P1 while awake, during anaesthesia with no movement observed, 8, 6, 4 and 2 min before and during intraoperative movements, and during emergence from general anaesthesia are presented in table 3. There was a significant increase in the latencies of Pa (+20%), Nb (+33%) and P1 (+43%) during anaesthesia, with no movement observed compared with the awake state. Before and during intraoperative movement and movement during emergence of anaesthesia, latencies of Pa, Nb and P1 did not change significantly compared with anaesthesia with no movement observed. Compared with the awake state, Pa increased significantly at 8 min and at 8, 6 and 2 min before movement, respectively; Nb and P1 latencies increased significantly 8, 6, 4 and 2 min before and during movement observed during operation, and during emergence from anaesthesia. Amplitudes of Na/Pa, Pa/Nb and Nb/P1 did not change significantly during anaesthesia with no movement observed, before and during movement observed during operation, and during emergence from anaesthesia.

Table 3 Mean (SD) latencies of V, Na, Pa, Nb and P1 (ms) and amplitudes of Na/ Pa, Pa/ Nb and Nb/P1 (µV) while awake, during maintenance of anaesthesia and during emergence from anaesthesia. *$P<0.05$ compared with awake

Discussion

There was no correlation in our study between physiological signs of wakefulness (increase in heart rate and arterial pressure) and motor signs of wakefulness during a combination of extradural analgesia with bupivacaine and general anaesthesia with midazolam. This observation may be explained by the extensive extradural block in all patients during surgery. It interfered with cardiovascular variables by attenuating arterial pressure responses. In this study we combined regional and general anaesthesia to provide analgesia and to minimize the effect of pain on the level of arousal.

There was a high incidence of movements during anaesthesia in our study. Twenty-five movements were observed in 10 patients; 15 movements in six patients were in response to commands indicating a high incidence of apparent consciousness during anaesthesia with midazolam. Nevertheless, to test consciousness we used simple questions ("open eyes", "move arms") that were not cognitively taxing. Simple commands followed by progressively more taxing commands, for example "squeeze your fingers twice", which require a more cognitively aware patient to achieve a positive response were not used. Therefore, these data did not discriminate between simple and complex responses. Only one patient had explicit recall of intraoperative events which may be explained by the amnesic effect of midazolam. Our observations agree well with data obtained by Russel.[10] Russell used an isolated forearm technique and found that 72% of patients receiving midazolam and alfentanil for general anaesthesia were conscious at some time during surgery. Russell could not demonstrate any relationship between autonomic signs by the PRST score and motor signs of wakefulness.

In our study, latencies of the peaks V, Na, Pa, Nb and P1 showed small SD values and corresponded well with peak latencies obtained under experimental conditions.[5 11] Relative amplitudes of the components Na/Pa, Pa/Nb and Nb/P1 were within the normal range also and showed greater inter-individual variability than latencies. During anaesthesia with midazolam, MLAEP were preserved compared with the awake state. MLAEP latencies increased only slightly while amplitudes did not decrease. Several investigators have demonstrated that the generators of MLAEP are located in the primary auditory cortex of the temporal lobe.[5 12–15] This leads to the conclusion that with midazolam, the neural generators in the primary cortex of the temporal lobes are not suppressed completely and cortical processing of auditory stimuli remains intact to some extent.

In contrast with midazolam, many anaesthetic agents suppress MLAEP. It is a well known observation that MLAEP typically show a dose-dependent increase in latencies and a decrease in amplitudes during anaesthesia with isoflurane, enflurane, halothane, sevoflurane, desflurane, etomidate, thiopentone, propofol and Althesin.[1–3 16–22] At approximately 1 MAC of the volatile anaesthetics, isoflurane, sevoflurane and desflurane MLAEP components were severely attenuated or suppressed almost completely. The latencies of the brainstem components of the auditory evoked potential were prolonged only slightly. Therefore, it has been suggested that MLAEP may be used to measure depth of anaesthesia and indicate intraoperative awareness.[6 7]

There are experimental data from several studies indicating a close relationship between MLAEP and intraoperative movements, intraoperative awareness and explicit and implicit memory functions during general anaesthesia. After bolus injections of thiopentone, MLAEP were suppressed immediately after induction of general anaesthesia. Amplitudes and latencies of the MLAEP returned to awake baseline values 4–6 min after administration of thiopentone when patients demonstrated motor signs of wakefulness.[18] In patients undergoing Caesarean section, MLAEP indicated periods of intraoperative wakefulness and correlated with postoperative recall of surgical manipulations.[23] Thornton and colleagues[6] and Newton and colleagues[7] studied the relation between MLAEP and response to verbal commands, conscious awareness and recall in surgical patients and anaesthetized volunteers during different sub-MAC concentrations of nitrous oxide and isoflurane. When MLAEP peak latencies were increased significantly compared with the awake state, no response to verbal commands, conscious awareness or recall were observed. In contrast, when MLAEP were increased only slightly during anaesthesia they found a high incidence of response to verbal commands, conscious awareness and recall. The AEP variables were related to the level of wakefulness and reflected episodes of wakefulness more closely than end-expiratory blood-gas concentrations. Furthermore, it was shown that during phases of intact MLAEP in patients undergoing cardiac surgery, presented acoustic information in the intraoperative period could be perceived and remembered implicitly in the postoperative interview although patients had marked amnesia for the intraoperative message.[24]

We conclude that a high incidence of motor signs of wakefulness and consciousness associated with preserved MLAEP indicate a high level of cortical neural activity and responsiveness during anaesthesia with midazolam. Our data agree with those of Russell who concluded that "this i.v. anaesthetic technique cannot be recommended for general use".[10]

Intradermal compared with prick testing in the diagnosis of anaesthetic allergy

M. McD Fisher and C. J. Bowey

Summary

We have tested the hypothesis that intradermal testing is a more effective method for determining the drug responsible for anaesthetic anaphylactic reactions than prick testing in 212 consecutive patients, aged more than 10 yr, referred to an anaesthetic allergy clinic over a 4-yr period. The study was a prospective, non-randomized design. Intradermal testing was conducted using a previously described method and diluted drugs, and prick testing using undiluted drugs (with the exception of opioid analgesics which were diluted 1:10). The tests were performed on individual patients' forearms on the same occasion. Patients were followed-up to determine the results of subsequent anaesthesia and the difference between tests was analysed using kappa and tau statistics. There was 93% agreement overall between the paired tests. Which test detected the drug responsible was dependent on diagnostic criteria for positivity. The differences between the tests were not statistically significant. Using both tests improved predictability by 67% (tau=0.67, $P<0.001$). We conclude that in the absence of data to support one test being superior, other factors influence the choice of test. Prick testing was cheaper, and the reduction in pain and trauma with prick testing makes it more suitable for children. However, there are no data available on the safety of subsequent anaesthesia based on the results of prick testing alone, and reliability with time has not been assessed. Intradermal testing may be easier for the infrequent user. Skin testing is valuable in the investigation of anaesthetic anaphylaxis whichever test is chosen. When there is doubt both tests should be performed. (*Br. J. Anaesth.* 1997; **79**: 59–63).

Key words
Allergy. Skin, tests. Complications, anaphylaxis.

The use of skin testing to verify the anaphylactic aetiology of an adverse event during anaesthesia, establish the drug responsible and predict the safety of alternative drugs has been validated in several studies.[1–7] The high incidence of positive radioimmunoassay (RIA) tests for specific IgE to induction agents and neuromuscular blocking drugs in patients with positive skin tests[8 9] suggests that these tests demonstrate IgE antibodies to drugs which give positive tests and that the reactions in which the tests are positive are IgE-mediated.

Controversy persists as to the best method of skin testing. Intradermal testing has been used in the majority of studies, although three studies have demonstrated that prick testing has a similar efficacy.[10–12] In a prospective comparison of prick and intradermal testing in the same patients, Leynadier and colleagues[11] suggested that prick testing was the better test although seven of 50 reactors with positive intradermal tests had negative prick tests. Laxenaire and colleagues found no difference in the results in 34 patients using serial dilutions of drugs.[10]

To evaluate these tests further, we have investigated prospectively 212 patients referred to an anaesthetic allergy clinic for investigation of possible anaesthetic allergy.

Patients and methods

Over a 4-yr period, we investigated 212 consecutive adult patients referred to the anaesthetic allergy clinic. Children less than 10 yr of age and patients who allegedly reacted to local anaesthesia were excluded. The hospital Ethics Committees did not require informed consent for testing as it was considered that both tests were valid diagnostic tests.

For intradermal testing, drugs were freshly diluted in normal saline the day of the test and testing was performed using a design described previously.[2] Table 1 shows the dilutions used for the first 102 patients (group I) and the second 110 patients in whom dilutions of the neuromuscular blocking drugs were increased (group II) to determine if this affected the results of testing. All drugs used before the reactions were tested, and in the case of neuromuscular blocking agents the other available blockers were tested. This availability varied over the course of the study. Gallamine was used only if it had been administered before the reaction.

Midazolam	5 mg ml^{-1}	1:100	1:100	Undilute	1
Suxamethonium	50 mg ml^{-1}	1:1000	1:500	Undilute	167
Alcuronium	5 mg ml^{-1}	1:1000	1:500	Undilute	166
Atracurium	10 mg ml^{-1}	1:10000	1:1000	Undilute	145
Tubocurarine	10 mg ml^{-1}	1:10000	1:1000	Undilute	143
Gallamine	40 mg ml^{-1}	1:1000	1:500	Undilute	4
Vecuronium	4 mg ml^{-1}	1:1000	1:500	Undilute	146
Pancuronium	2 mg ml^{-1}	1:1000	1:500	Undilute	144
Neostigmine	2.5 mg ml^{-1}	1:1000	1·1000	Undilute	7
Atropine	0.6 mg ml^{-1}	1:1000	1:1000	Undilute	10
Cephalothin	100 mg ml^{-1}	1:100	1:100	Undilute	7
Cefotaxime	50 mg ml^{-1}	1:100	1:100	Undilute	1
Haemaccel	3.5 mg ml^{-1}	1:100	1:100	Undilute	5
Dextran 70	6 mg ml^{-1}	1:100	1:100	Undilute	2
Histamine	1:50	1:50	1:50	Undilute	170
Droperidol	10 mg/2 ml	1:100	1:100	Undilute	3
Penicillin	1 000 000 u/5 ml	1:100	1:100	Undilute	3
Protamine	500 mg/10 ml	1:1000	1:1000	Undilute	2
Gentamicin	80 mg/2 ml	1:100	1:100	Undilute	3

For prick testing, the drug solution was placed on the ventral aspect of the forearm and the epidermis pricked through the solution using a 25-gauge needle, bevel uppermost at 45 °C to the skin, to a depth at which the skin could be lifted. Morphine, papaveretum and pethidine were diluted 1:10 in saline as preliminary studies suggested that false positives were caused by these drugs if undiluted. All other drugs were undiluted (table 1).

For intradermal testing, a positive result was recorded for a persistent wheal of greater than 0.8 cm and for the prick testing a positive result was recorded for a wheal of greater that 0.4 cm. If the test was positive for a drug administered before the reaction being investigated the result was recorded as diagnostic, that is caused by that drug. The agreement between tests was assessed statistically using Kappa[13 14] and Tau[15] tests.

All patients were given a letter describing the event and the results of testing, and details of subsequent anaesthesia were sought.

The patients were divided in four groups: *minor reactions*—29 patients had reactions confined to the skin, or systemic reactions which resolved rapidly without treatment; *severe reactions*—135 patients had systemic reactions requiring treatment with vasoactive drugs; 129 of these were felt by the anaesthetist to have been life threatening; *preoperative*—13 patients were referred because of multiple allergies and were to undergo anaesthesia; *not anaphylactic*—35 patients had single system reactions in which another cause (assessed by an independent physician from the history) was likely.

Results

The results for all patients are shown in table 2. Overall there was agreement for 1294 (93%) comparisons and disagreement for 98 (7%); there was no significant difference between the agreement in the different groups.

The highest diagnostic yield was in patients with severe reactions in which a diagnosis was made in 116 of 135 patients. The majority of these patients reacted to neuromuscular blocking drugs (93 patients), and the other drugs implicated by skin testing were induction agents (13 patients), induction agent with neuromuscular blocking agent (two patients), antibiotics (three patients) opioid analgesics (three patients)and Haemaccel (two patients). Intradermal testing in this group was positive for more drugs than prick testing overall, but less when

Table 2 Prick testing and intradermal testing in 212 patients: overall results

prick test results were considered positive if wheal size was less than 4 mm (table 3). This increase with prick testing was not statistically significant. The agreement between intradermal and prick teasing was substantial in the severe group (kappa=0.7) and excellent overall (kappa=0.8).

In spite of this degree of agreement, the tau analysis suggested a 50% reduction in predictive error if both tests were used in the severe group (tau=0.5, $P<0.001$) and a reduction in predictive error of 67% if both tests were used in all patients (tau=0.67, $P<0.001$).

The majority of disagreement in reactions to neuromuscular blocking drugs was not in the drug responsible but in the detection of cross sensitivity to other neuromuscular blocking agents. In the severe group of patients, increasing the concentration of neuromuscular blocking agent did not alter significantly the diagnostic yield of the test (kappa=0.73 *vs* kappa=0.68) (table 4).

Details of subsequent anaesthesia were obtained in 124 patients (table 5). One patient had a second reaction. This patient, who reacted to pancuronium, had positive prick and intradermal tests to pancuronium and a subsequent reaction to which we attributed to alcuronium on the basis of history. Both tests were negative for alcuronium after both reactions. One patient had a minor systemic reaction after testing with thiopentone and histamine only, and this responded to adrenaline 0.2 mg s.c.

Discussion

The major problem with studies of this nature is that there is no absolute measure with which to compare the results.[16] Thus when there is disagreement it is not possible to tell which test is correct, without subjecting the patient to the hazards of challenge. As RIA tests are less sensitive and specific than skin tests,[16] they are not suitable to discriminate between tests which disagree, although when positive for an individual drug they add support to the skin test diagnosis.

We have shown previously that basing subsequent anaesthesia on diagnosis and detection of cross sensitivity from intradermal testing is usually reliable, with only three anaphylactic reactions in subsequent anaesthesia in 234 patients who had life-threatening reactions before testing.[16] The data from this study confirm that in patients with anaphylaxis during anaesthesia, subsequent anaesthesia based on the results of prick and intradermal testing is usually, but not always, safe. There have been no published studies showing the safety or otherwise of subsequent anaesthesia based on the results of prick tests alone.

Galletly[17] suggested that the dilutions chosen in our studies for intradermal testing (which were chosen by determining dilutions that did not cause wheals as a result of direct histamine release in volunteers) were greater than necessary. This could be a source of false negative results. Increasing the concentrations of neuromuscular blocking agents for intradermal testing did not significantly alter the diagnostic value of the test but increased the discrepancy between prick and intradermal tests for other neuromuscular blocking agents. The majority of this increase was related to reactions to the potent cutaneous histamine releasers tubocurarine and atracurium.

The diagnostic criteria for positivity were fulfilled more often by intradermal testing than by prick testing when a positive result for prick testing was a wheal greater than 4 mm. Moneret Vautrin and Laxenaire[18] have suggested that any wheal should be considered positive for prick testing and, using this criterion, prick testing produced a diagnostic result more commonly than intradermal testing. It cannot be determined however whether this was an increase in false positives or true allergy detected. Both tests produced more diagnoses than each test alone, and the statistical analysis suggested the safety of subsequent anaesthesia would be improved by performing both tests.

There is little to choose between each test on the basis of the above data in which a single intradermal test was used for each drug, rather than the serial dilutions used in the French study which showed 100% agreement in 38 patients.[10] It is possible that using serial dilutions rather than a single injection would increase the diagnostic value of intradermal testing even further.[10 18]

Prick testing has advantages over intradermal testing: it is cheaper than intradermal testing (by approximately 25% in our unit); the reduced pain and trauma of prick testing makes it more suitable for use in children; and it is said to be safer.[18] There are no data to support this view for anaesthetic drugs. Indeed the low incidence of systemic reactions to skin testing after anaesthetic reactions (three in more than 1200 patients in our series) would imply that a very large study is necessary to show a significant difference.

It has been suggested that intradermal tests are more likely to produce false positives than prick tests.[18] This would favour the use of intradermal tests, as a false positive test inconveniences the anaesthetist and does not carry the risk of anaphylaxis of a false negative test.[8] Intradermal testing is more reliable in propofol reactions.[19]

Intradermal testing has been validated in repeat studies over time[20 21] but no data are available for prick testing. The study of Leynadier, Sansarricq and Dry[21] suggested that the persistence of positive tests was insufficiently reliable on which to base subsequent drug selection and further preoperative skin tests should be performed, but our own study[20] and the anaesthetic follow-up of allergic patients,[16] suggest that the positive tests persist for up to 30 yr and preoperative testing is only mandatory if untested drugs to which the patient may show cross sensitivity are to be used.

One other practical factor worthy of consideration is ease of performance. We believe that the anaesthetist who is not regularly testing patients would find intradermal testing easier to perform and interpret.

It is important to emphasize that history is also very important in the follow-up of patients with possible anaesthetic allergy. In 19 patients with a severe reaction in whom a diagnosis was not made with skin testing, a diagnosis could be made from history or RIA testing in 17 of 19 cases. In six patients with a negative skin test, the diagnosis could be made from the history as only one drug was administered within 10 min of the reaction. Two patients had negative cutaneous responses to histamine controls and had a diagnosis made by RIA testing. One patient who had previous skin and RIA testing was re-tested 7 yr later and all tests were negative; we concluded that sensitivity had been lost. Two patients had strongly positive RIA and skin tests for neuromuscular blocking agents other than the one administered and one patient who had reacted to decamethonium and suxamethonium on separate occasions had strongly positive RIA to suxamethonium and positive skin tests to decamethonium only. She was not re-tested with decamethonium as it is no longer available. (She has subsequently had a positive intradermal test to suxamethonium 3 yr later.) In these three patients we suggested that all positive drugs and the one used should be avoided.

Three other patients had intradermal tests implicating a drug used, but not reaching the criterion for positivity in this study, and were warned against the drugs suggested. One patient had a negative mast cell tryptase test and negative skin tests, making an anaphylactic aetiology unlikely. One patient, who was tested only for thiopentone and histamine as thiopentone was the sole agent used, had negative skin tests but a mild anaphylactic reaction. In only two patients who had severe reactions could no aetiological agent be found. Both of these patients and 15 of the others who did not the meet criteria for positive skin tests have undergone subsequent uneventful anaesthesia.

In patients referred before operation, one patient had a positive prick test but not intradermal test to three drugs and one patient had a positive intradermal test but not a prick test to three neuromuscular blocking agents. These drugs were avoided for anaesthesia which was uneventful in all patients.

We conclude that patients who have severe reactions during anaesthesia which might be allergic should undergo skin testing. There was no significant difference in the reliability of diagnostic yield of intradermal or prick testing, and the choice of test could be based on other factors such as age of the patient, cost, ease of performance, unreliability of prick testing with propofol, lack of data on reliability of prick testing with time and outcome of subsequent anaesthesia in allergic patients when drug choice is based on prick testing. If the results of either test is negative or equivocal, intradermal and RIA testing should be performed. Where there are conflicting results all drugs which give positive tests by either method should be avoided.

The results of skin testing should be communicated in a letter stating drugs given, what happened, results and conclusions. The results of subsequent anaesthesia should be documented in the patient's letter and the file letter.

In reactions to neuromuscular blocking agents, the results agreed better for detecting the drug responsible for a reaction than determining cross sensitivity to other neuromuscular blocking drugs. It is sensible to suggest avoiding all neuromuscular blocking agents that may be positive as cross sensitivity occurs in 60% of patients.[16 22]

Safe subsequent anaesthesia is usual but not guaranteed when patients, who have had adverse reactions which may be allergic, receive drugs suggested to be safe on the basis of skin tests and history.

Plasma dilution and the rate of infusion of Ringer's solution

R. G. HAHN AND C. SVENSÉN

Summary

Changes in the volume of the fluid space expanded by i.v. infusion of Ringer's acetate solution have been analysed recently using mathematical models. Data obtained by such analyses allow simulation of the dilution of the plasma volume during infusion of the solution at different rates. To obtain basic kinetic data for such simulations, the plasma dilution–time curves were measured during and after i.v. infusion of Ringer's solution 25 ml kg^{-1} over 30 min in 15 healthy male volunteers (mean age 31 yr) and over 30, 45 and 80 min in six females (mean age 32 yr). Based on these experiments, nomograms were constructed from which the rate of infusion of Ringer's solution and the infusion time required to obtain a defined plasma dilution in both males and females can be estimated together with the infusion rate needed to maintain the dilution at the level reached. (*Br. J. Anaesth.* 1997; **79**: 64–67).

Key words
Fluids, i.v. Fluid therapy. Fluid balance. Blood, haemodilution. Model, pharmacokinetic.

I.v. volume loading is frequently carried out by anaesthetists. The fluid load is usually given at a high rate to prevent circulatory instability before induction of spinal and extradural anaesthesia. Many anaesthetists also give a fluid load before general anaesthesia. However, the infusion rate required to rapidly expand the blood volume to a predetermined degree is largely unknown.

We have used a recently developed pharmacokinetic model adapted for body fluid spaces[1 2] to simulate the infusion rates required to effectively obtain and maintain a defined dilution of the plasma volume with Ringer's solution in healthy males and females. Our purpose was to open up the possibility of optimizing i.v. fluid therapy in clinical practice by setting a predetermined dilution of the plasma volume as the therapeutic goal. Volume expansion is the product of this dilution and baseline plasma volume. The kinetic data required for the simulations were obtained from volunteer experiments in which Ringer's's acetate solution was infused i.v.

Subjects and methods

MALE VOLUNTEERS

We studied 15 healthy men, aged 25–36 yr (mean 31 yr), weighing 65–100 kg (mean 78 kg). The study was approved by the local Ethics Committee and informed consent of all subjects was obtained.

Ringer's acetate solution 25 ml kg^{-1} (Pharmacia, Uppsala, Sweden) was given at a constant rate over 30 min via one or several infusion pumps (IVAC 560, San Diego, CA, USA). The ionic content of this solution is (in mmol $litre^{-1}$): Na^+ 130, K^+ 4, Ca^{2+} 2, Mg^{2+} 1, acetate 30 and Cl^- 110. Before any fluid was given, a cannula was placed in the cubital vein of each arm for blood sampling and infusion of fluid.

Venous blood was collected every 5 min for 3 h and blood haemoglobin concentration was measured using a Technicon H 2 (Bayer, Tarrytown, NY, USA) with a coefficient of variation of 1.3%. The first sample was obtained in duplicate and the mean value was used in calculations.

FEMALE VOLUNTEERS

Six female volunteers, aged 23–46 yr (mean 32 yr), body weight 50–75 kg (mean 60 kg) received 24 infusions of Ringer's solution. Under the same basic conditions as in the males, the volunteers were given, in random order and at intervals of at least 1 day, 25 ml kg^{-1} of this fluid over 30, 45 and 80 min.

Samples for measuring blood haemoglobin concentration on a Coulter Counter STKS (Counter Electronics, Hialeah, Fla., USA) were obtained from the venous cannula not used for infusion, before infusion, every 10 min during infusion and at 0, 5, 10, 15, 20, 25, 30, 60, 80, 100 and 120 min after infusion. The first haemoglobin sample in the series was obtained in duplicate and the mean was used in calculations.

In females, Ringer's solution was also infused very rapidly (100 ml min^{-1} over 15 min). However, these results were not used as the infusions caused symptoms, and therefore could not be used clinically. The results also differed from those at the slower infusion rates, which indicates that a different state exists when Ringer's solution is infused very rapidly. Details of these experiments are given elsewhere.[2]

DATA ANALYSIS

Data on haemoglobin concentrations were analysed according to the one-volume fluid space (VOFS1) model which assumes that the infused fluid is distributed in a single well-stirred body fluid space.[1] Fluid is infused at a constant rate (k_i) and enters the body fluid space having the volume (v), which changes as a result of fluid leaving the space at a basal rate (k_b) and at a controlled rate (k_r) proportional to the deviation from the target value (V). Based on these assumptions, the following equation describes the volume change of the body fluid space expanded by the infusion:

$$dv/dt = k_i - k_b - k_r\,(v - V)/V$$

During (d) and after (a) infusion, the solution to this differential equation is:

$$w_d\,(t) = [(k_i - k_b)/k_r]\,(1 - e^{-k_r t/V}),\ 0 \leqslant t \leqslant t_1$$

$$w_a\,(t) = [-k_b/k_r]\,(1 - e^{-k_r (t-t_1)/V}) + w_d\,(t_1)\,e^{-k_r (t-t_1)/V},\ t_1 \leqslant t \leqslant \infty$$

where $w(t)$ is the dilution $(v(t) - V)/V$.

The random search method was chosen for the least-squares fitting procedure to obtain the best estimates of the unknown variables in the model (V and k_r), whereas k_b (basal fluid loss) was set to 1 ml min^{-1}.

Plasma dilution over time was simulated by setting these variables to the mean values for the respective groups of volunteers studied. For males, V was 6.61 litre (95% confidence interval 5.34–7.89 litre) and k_r 148 (95–201) ml min^{-1}. For females, we used 4.09 (3.44–4.74) litre and 111 (79–142) ml min^{-1}, respectively.

Simulations were performed in two steps, using Matlab version 4.2 (Math Works, Notich, MA, USA). The first step studied the infusion rate and infusion time required to obtain a definitive plasma dilution. The purpose of the second step was to maintain the dilution already obtained at a steady-state level (fig. 1). The required infusion rate is then dependent on the mode by which the infusion was given initially.

A two-volume fluid space model (VOFS2) has also been developed. In that model, the rate of volume equilibration between a primary and secondary fluid space is proportional to the difference in the relative deviation from the target value. Fitting the dilution–time curves to both VOFS1 and VOFS2 sometimes indicates that the latter model significantly reduces the mean square error. In particular, this occurs when urinary excretion in response to infusion is small.[2] Only VOFS1 is used here because it is difficult to know, in the clinical setting, for which patient VOFS2 is statistically justified. However, we undertook simulations also with VOFS2 in order to evaluate the magnitude of the error inflicted by the fact that some infusions are described better by the two-volume model.

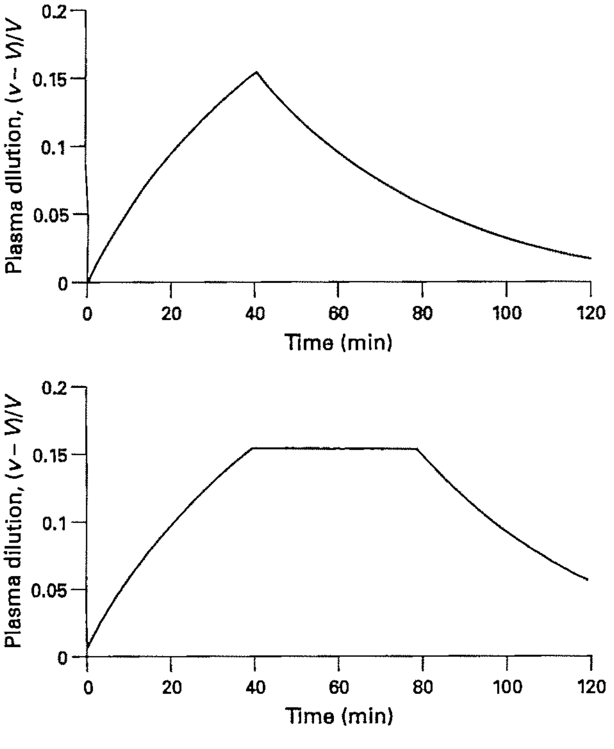

Figure 1 Examples of simulated plasma dilution–time curves in males performed in two steps, with step one (top), followed by step two where steady state is maintained (bottom). Ringer's solution is first given at a rate of 40 ml min^{-1} over 40 min and then discontinued. In step two, dilution is maintained using an infusion rate of 25 ml min^{-1}.

Results

The nomograms for men and women are shown in figures 2 and 3, respectively. In both cases, the first part of the fluid loading phase, when plasma dilution increased, was obtained from the left half of the nomogram. When the appropriate dilution is found, we trace the horizontal to the right half of the figure (along the same infusion rate line) to the line corresponding to the infusion time used. Thereafter, the steady-state infusion rate is given by the vertical correlation.

Consider that a male patient receives an infusion of Ringer's solution at a rate of 30 ml min^{-1} for 30 min (900 ml), after which a steady-state dilution is desired. The left nomogram indicates that dilution of plasma volume is close to 10%. The infusion rate that leads to a steady state is 15 ml min^{-1} and is given in the right half of the nomogram.

An example of how dilution of plasma volume by 15% can be found and maintained is shown in figure 1.

The nomograms were based on the VOFS1 model despite the fact that VOFS2 was statistically justified in 10 of the 15 experiments in males and in eight of the 24 experiments in females. In males, however, the times required to reach any target dilution when VOFS2 was applied differed by only ±2 min from those indicated by our nomogram. This difference was somewhat greater in females. With VOFS2, a plasma dilution of 5–15% was reached 2–5 min faster than that indicated by our nomogram. At the extreme, this difference amounted to 7–15 min when

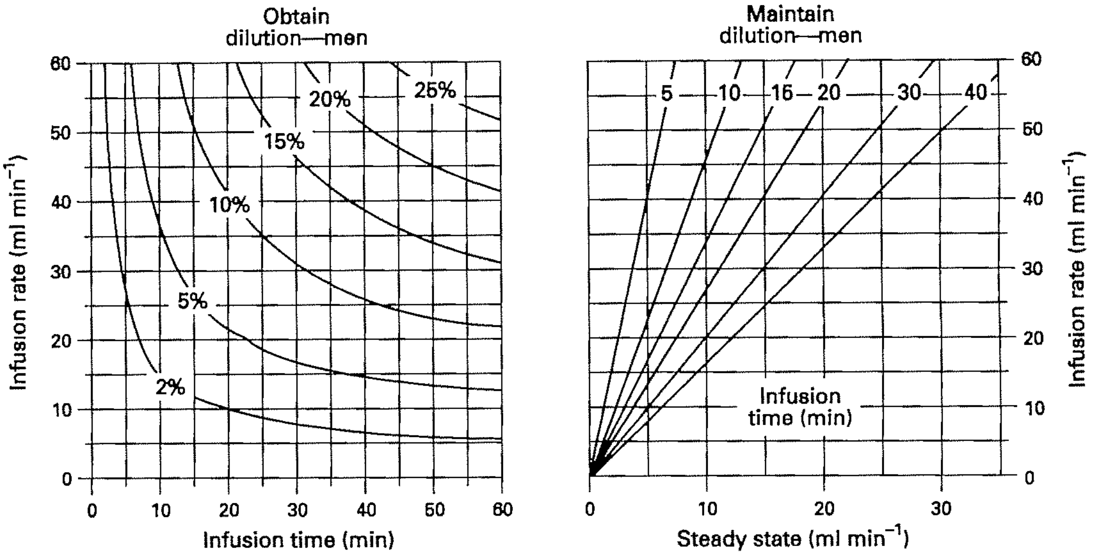

Figure 2 Nomograms for men showing the relationship between infusion rate and infusion time (left) and where the infusion rate required to maintain a steady-state dilution during a subsequent phase can be estimated by entering the initial infusion rate and infusion time used during the first phase (right).

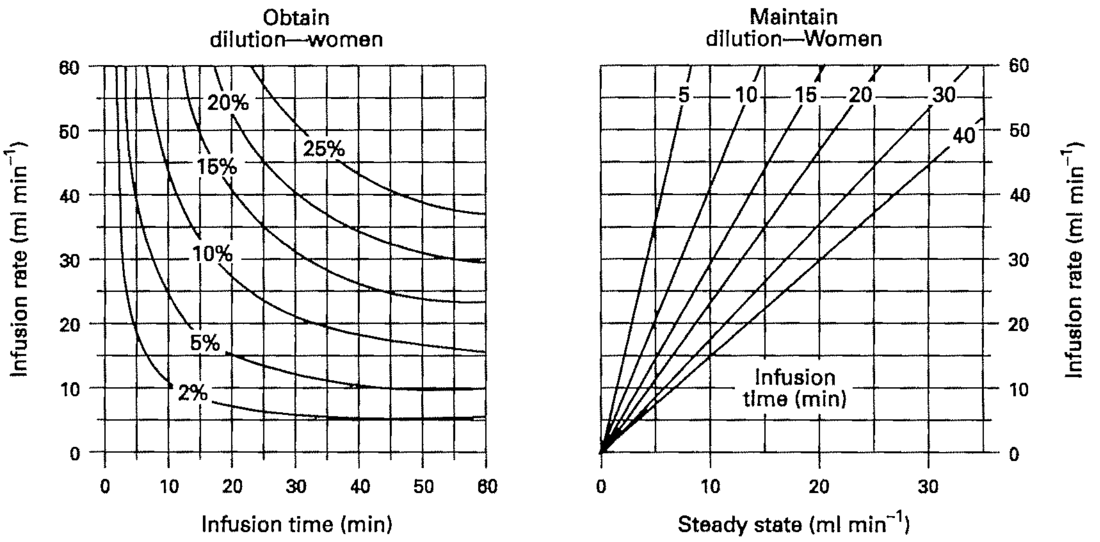

Figure 3 Same nomograms for women as those described for men in figure 2.

a low infusion rate was used to obtain a dilution of 20–25%.

Discussion

The purpose of carrying out fluid loading with Ringer's solution is to increase plasma volume by haemodilution. A defined fluid load is usually given over a specific time without an end-point being specified. We suggest that dilution of blood would be a suitable end-point as the volume expansion effect of the fluid is believed to be an important therapeutic goal. We have outlined the possibilities and limitations of this practice in an experimental situation. The nomograms we have constructed allow estimation of the infusion rate and time required to both obtain and maintain a defined dilution of plasma volume. They show how alternative fluid regimens can be found, all of which lead to the same defined dilution of plasma volume.

Although the nomograms quantify what the anaesthetist intuitively knows and does, the computer simulations made us realize that marked haemodilution is difficult to obtain in healthy awake humans. For example, the infusion rate must be at least 50 ml min^{-1} in a young man to yield a plasma dilution of 20%, which corresponds to an increase in blood volume of approximately 10%. Even at this high rate, the infusion has to continue for 40 min (and requires 2000 ml of fluid) to yield the desired dilution. In contrast, an infusion rate below 40 ml min^{-1} is not capable of diluting plasma volume by 20%, regardless of how long the infusion is continued. When fluid is infused at a high rate, it does not matter if the simulation is based on VOFS1 or VOFS2.

The difficulty in achieving pronounced haemodilution can be explained in part by rapid elimination of fluid. In the volume kinetic model, urinary excretion is proportional to plasma dilution, an assumption which receives support from the overall good agreement between measured urine volume and model-predicted urinary excretion.[2] Furthermore, compliance of the vascular system for volume expansion may prevent excessive haemodilution. When the rate of infusion of Ringer's solution is increased to 100 ml min^{-1}, haemodilution no longer increases. At this point, compliance is probably lower in the circulation than in the interstitial fluid space, and further infused fluid accumulates there. In our model, such accumulation of fluid is noted as an increase in the expandable fluid space (V). One should note, however, that haemodilution increases further if the patient's vascular status is changed, such as by extradural anaesthesia[3] or blood loss.[4] Therefore, the use of the nomograms derived in this study should be restricted to volume loading carried out before anaesthesia is induced. Furthermore, the volume kinetic data should not be extended to infusion rates higher than those used here.

The amount of fluid required for carrying out a fluid load can be estimated readily from the nomograms. Such calculations show that a fast infusion is more effective than a slow one. Imagine we wish to increase plasma volume by 10%, which corresponds to an increase in blood volume of 5%. In males, this can be achieved by infusing Ringer's solution at a rate of either 50 ml min^{-1} for 15 min (750 ml) or 25 ml min^{-1} for 45 min (1125 ml). The second infusion regimen requires 50% more fluid than the first despite the fact that the same dilution is obtained.

Nomograms were constructed for males and females separately as there seems to be sex-related differences in volume kinetics. Body weight and elimination rate constant (k_r) for Ringer's solution were 30% higher in males than in females and the size of the expandable fluid space (V) was 60% higher. These differences explain why marked dilution requires much higher infusion rates in men. Modest degrees of dilution, however, can be obtained by almost the same infusion rates as in women. The right parts of the nomograms ("maintain" dilution) are also similar for males and females, but one must remember that most infusion rates result in more pronounced dilution of plasma volume when Ringer's acetate is given to females.

The difference in V between the sexes can probably be explained by the larger body weight and greater percentage of water in the extracellular space, which amounts to 200 ml kg^{-1} of body weight in men compared with 150 ml kg^{-1} in females.[5] It is important to note, however, that our nomograms are not based on the size of the extracellular space but on the body fluid space that is actually expanded by Ringer's solution (V). This fluid space is different from the volume in which the same fluid is distributed and usually amounts to about twice the plasma volume. The concept of an expandable fluid space is relevant to emergency medicine, trauma care, anaesthesia and surgery, as V indicates hydration of the body resulting from i.v. fluid therapy.

LABORATORY INVESTIGATIONS

Beneficial effect of concomitant administration of isoflurane and nicorandil

V. Piriou, S. Ross, D. Pigott, R. Evans and P. Foex

Summary

In common with halogenated anaesthetics, nicorandil, a new K_{ATP} channel opener, has been shown to have cardioprotective and vasodilator effects. Recent studies have also suggested that the vasodilator and protective effects of halogenated anaesthetics are mediated partly via K_{ATP} channel opening. This study examined the effects of concurrent administration of nicorandil and isoflurane on haemodynamic state and ventricular function before, during and after 15 min of ischaemia. We studied left ventricular function in 40 anaesthetized rabbits using ultrasonomicrometry. Measurements were obtained before, during and after 15 min of regional ischaemia. Regional ventricular function was assessed in terms of systolic shortening (SS%) and preload recruitable work area (PRWA, the area beneath the regional stroke work *vs* end-diastolic length relationship) during reperfusion. Four groups were studied: group F (n=10) received a bolus dose of fentanyl 100 μg kg^{-1} and then 400 μg kg^{-1} h^{-1} throughout; group I (n=10) received 2.05% end-tidal concentration of isoflurane (1 MAC); group FN (n=10) received fentanyl, a bolus does of nicorandil 100 μg kg^{-1} and then 25 μg kg^{-1} min^{-1}, 15 min before occlusion; and group IN (n=10) received isoflurane and nicorandil. Isoflurane decreased left ventricular systolic pressure and ventricular contractility (+dP/d$t$max, slope of preload recruitable stroke work, and SS%). Nicorandil increased +dP/d$t$max in group FN. Post-ischaemic regional left ventricular contractility in group I did not differ from that in group F, however, groups receiving nicorandil recovered to a greater extent. Group IN showed better recovery compared with all other groups when ventricular contractility was assessed by PRWA normalized to pre-occlusion values (mean 99.3 (SEM 10.5) % *vs* 73.4 (7.5) %, 50.2 (5.8) % and 52.4 (3.7) % at 120 min reperfusion in groups FN, I and F, respectively). Tissue ATP and lactate contents did not differ between groups. We conclude that concurrent administration of nicorandil and isoflurane enhanced post-ischaemic recovery compared with isoflurane anaesthesia or nicorandil and fentanyl administration. (*Br. J. Anaesth.* 1997; **79**: 68–77).

Key words
Anaesthetics volatile, isoflurane. Heart, myocardial function. Pharmacology, nicorandil. Heart, nicorandil. Rabbit.

Nicorandil, a nicotidamide ester, is a potassium channel opener used in clinical practice for antianginal therapy.[1] This drug exhibits several actions, including vasodilatation, mediated by both nitrate radical and opening of K_{ATP} channels, and a cardioprotective effect, attributed mainly to opening of K_{ATP} channels.[2 3]

Isoflurane is a vasodilator and also a cardiodepressant and protective agent.[4] Recent investigations have shown that isoflurane-induced coronary vasodilatation[5] and its cardioprotective effect[6] are antagonized by glibenclamide, and therefore may be mediated partly by K_{ATP} channels.

With the possibility that the number of angina patients on long-term nicorandil treatment undergoing surgery and general anaesthesia will increase in the future, this study was designed to investigate the potential effects of concurrent administration of isoflurane with nicorandil and of fentanyl with nicorandil. Haemodynamic state and regional myocardial function before ischaemia, and the time course of functional regional recovery after 15 min of regional ischaemia were studied in an anaesthetized, open chest rabbit model.

Materials and methods

SURGICAL PREPARATION OF ANIMALS

The study conformed to UK Animals Acts (Scientific Procedures, 1986). We studied 73 New Zealand White rabbits of both sexes (2.5–3.5 kg) premedicated with xylazine 1 mg kg^{-1} i.m. and anaesthetized with ketamine HCl 75 mg kg^{-1} i.m. Adequate depth of anaesthesia was ensured before any surgical procedure by absence of pedal and palpebral reflexes. The marginal ear vein was cannulated (20-gauge cannula) for administration of fluids (hetastarch 3 ml kg h^{-1}) and drugs. The central ear artery was also cannulated (18-gauge cannula) and connected to a pressure

transducer (Druck Ltd, Groby, Leicester, UK) for measurement of arterial pressure during surgery. All catheters were flushed with heparinized saline 10 u. ml^{-1} to prevent clotting during the experiment. A tracheotomy was performed (tracheal tube size 4 mm od) and the lungs of the rabbits were ventilated mechanically (Servo ventilator 900B, Siemens-Elema, Sweden) with 100% oxygen. Tidal volume was set at 15 ml kg^{-1} and ventilatory frequency at 35 bpm. Ventilation was adjusted to maintain $P\text{CO}_2$ in the physiological range. End-tidal gas concentrations were measured continuously (gas analyser M1025A, Hewlett Packard, Bracknell, UK). Body temperature was recorded using the thermistor of a 7F pulmonary artery catheter (Swan-Ganz, American Edwards Laboratories, Anasco, Puerto Rico) inserted orally into the oesophagus and maintained at 39.0–40.5 °C. Limb lead II of the electrocardiogram was monitored continuously using subcutaneous needle electrodes. Anaesthesia was maintained with a bolus dose of fentanyl 100 μg kg^{-1} followed by an infusion of 400 μg kg^{-1} h^{-1} during surgery and the stabilization periods. The heart was exposed via a left thoracotomy and suspended in a pericardial cradle. A 5-0 Dexon suture was passed around the major marginal branch of the left coronary artery approximately halfway between the apex and base and the suture ends threaded through a small vinyl tube to make a coronary snare. Where possible we tried to avoid snaring coronary veins but in some experiments this was not possible. A thin piece of rubber tubing was placed around the inferior vena cava to perform caval occlusions. Pressure in the left ventricle was measured by inserting a 16-gauge cannula into the apex of the left ventricle and connecting this to a micromanometer-tipped 8F catheter (Millar, Houston, TX, USA) through a tight adapter. This device was compared, in our laboratory, during *in vivo* simultaneous pressure measurements with an 8F micromanometer-tipped catheter placed directly in the cavity of the left ventricle. The time lag between the two devices did not exceed 2 ms and the differences in pressure values were <1%. *In vitro* measurements showed an undamped natural frequency of 66.6 Hz and a damping coefficient of 0.141. This 16-gauge cannula was used to minimize impairment in regional myocardial function. Two piezoelectric crystals (0.8 mm diameter, Triton, San Diego, CA, USA) for ultrasonic measurement of segmental lengths were implanted in the endocardium in the apical region supplied by the snared marginal coronary artery parallel to the minor axis. These were implanted approximately 8 mm apart through epicardial stab wounds. At the end of the experiment the heart was excised rapidly and tissue samples obtained from the non-ischaemic region (above the coronary snare) and the ischaemic region (between the pair of crystals). These samples were frozen rapidly in a Wollenberger clamp cooled in liquid nitrogen and stored in liquid nitrogen for analysis of adenine nucleotides and lactate content.

MEASUREMENT OF TISSUE NUCLEOTIDES AND LACTATE CONCENTRATION

The frozen tissue samples were ground in liquid nitrogen and extracted with perchloric acid (6% w/v). The neutralized extracts were assayed for ATP,[7] ADP,[8] AMP[8] and lactate[9] using standard enzymatic techniques with a spectrophotometer (Lambda 3 UV/VIS spectrophotometer, Perkin Elmer Ltd, Beaconsfield, Bucks, UK).

Energy charge potential was calculated as follow[10]:

$$\frac{[\text{ATP}]+0.5[\text{ADP}]}{[\text{ATP}]+[\text{ADP}]+[\text{AMP}]}$$

STUDY PROCEDURE

Four groups of animals were studied (fig. 1) and all experiments were performed randomly. In all groups after surgery there was a stabilization period of 30 min, after which baseline measurements were obtained under fentanyl anaesthesia. After baseline measurements, recordings were obtained at 30, 45 and 60 min. The measurement at 60 min was taken as the pre-occlusion value used for normalization of contractility indices. One hour after baseline measurements, regional ischaemia was imposed for 15 min, followed by 120 min of reperfusion. During ischaemia, measurements were obtained at 5 and 15 min and during reperfusion at 5, 10, 15, 30, 60, 90 and 120 min.

In all groups, surgery and baseline measurements were performed under fentanyl anaesthesia. In the fentanyl group (group F, n=10), fentanyl was continued throughout the experiment. In the isoflurane group (group I, n=10) infusion of fentanyl was stopped after baseline measurements and 1 MAC of

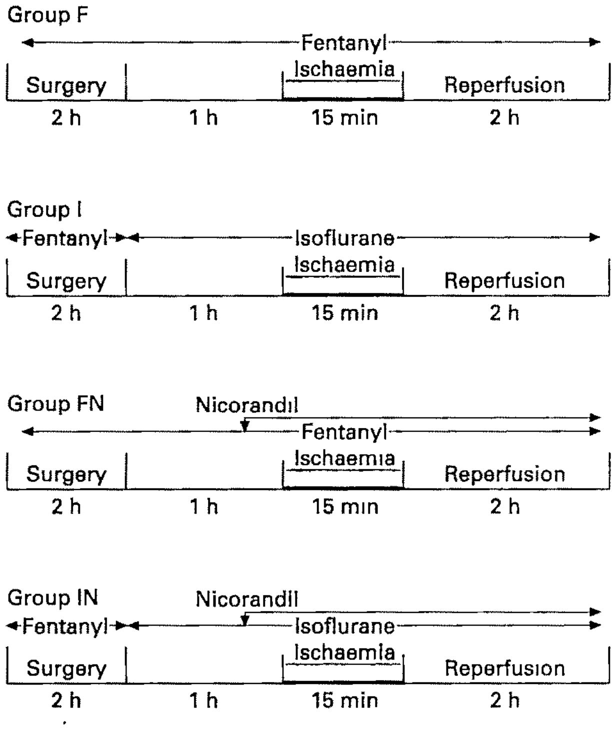

Figure 1 Study design.

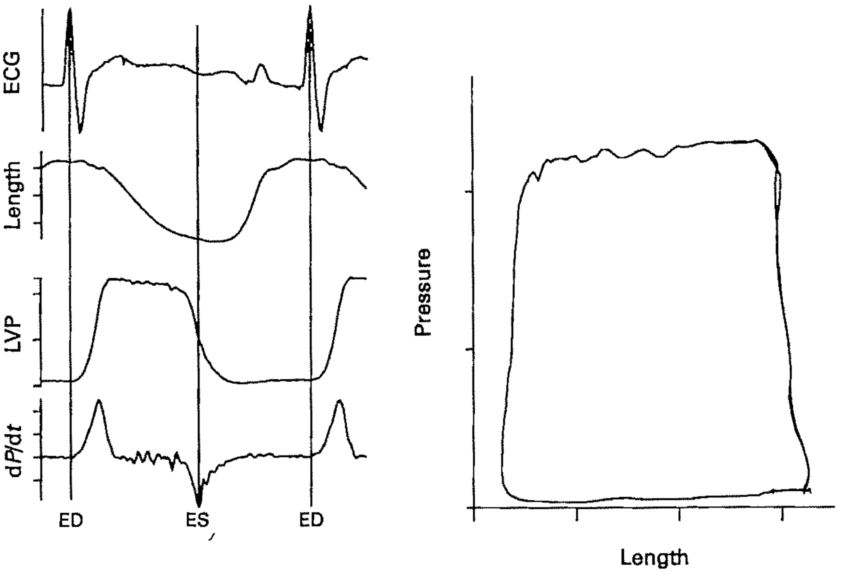

Figure 2 Signals obtained in one experiment before ischaemia. Left: ECG, apical length, left ventricular pressure (LVP) and d*P*/d*t*. The single cardiac beat is delineated by two end-diastolic lines (ED). End-systole (ES) was defined at peak negative d*P*/d*t*. Right: typical pressure–length loops.

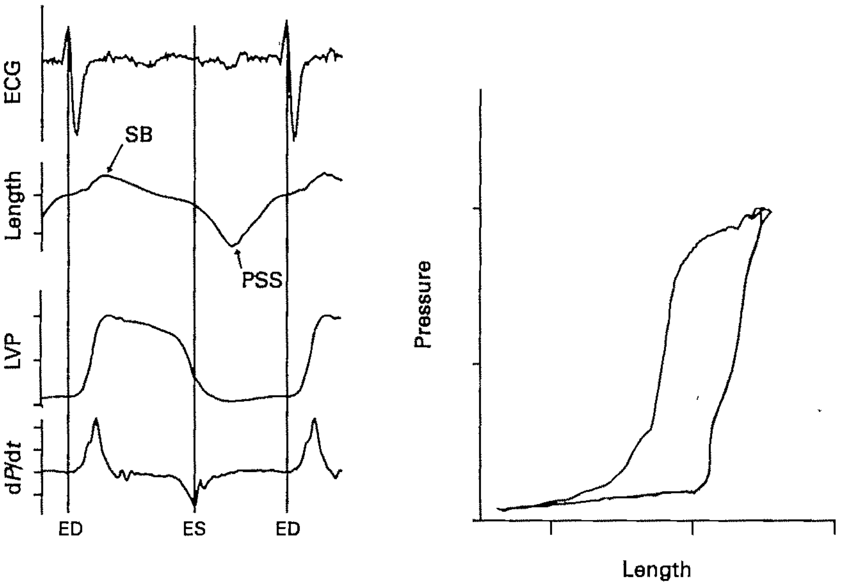

Figure 3 Signals obtained in one experiment during ischaemia. Left: ECG, apical length, left ventricular pressure (LVP) and d*P*/d*t*. The single cardiac beat is delineated by two end-diastolic lines (ED). End-systole (ES) was defined at peak negative d*P*/d*t*. Ischaemic length signal displays post-systolic shortening (PSS) and systolic bulging (SB). Right: typical pressure–length loops. The ischaemic pressure–length loop leans to the right.

isoflurane (2.05% end-tidal concentration)[11] introduced and continued for the duration of the experiment. In the fentanyl and nicorandil group (group FN, $n=10$) infusion of fentanyl was continued throughout the experiment and a bolus does of nicorandil 100 μg kg^{-1} followed by infusion of 25 μg kg^{-1} min^{-1} were started 15 min before coronary occlusion and continued for the duration of the experiment. In the isoflurane and nicorandil group (group IN, $n=10$) infusion of fentanyl was stopped after baseline measurements and 1 MAC of isoflurane introduced and continued for the duration of the experiment. A bolus dose of nicorandil 100 μg kg^{-1} followed by infusion of 25 μg kg^{-1} min^{-1} were started 15 min before coronary occlusion and continued for the duration of the experiment.

To produce ischaemia, the coronary snare was tightened by pulling the silk through the tubing. A bolus dose of lignocaine 0.7 mg kg^{-1} was infused just before coronary occlusion to prevent ventricular arrhythmias during ischaemia and reperfusion. Ischaemia was confirmed by changes in the shape of the pressure–length loop (reduction in systolic shortening, increase in post-systolic shortening and/or systolic bulging) (figs 2 and 3). Visually, myocardial ischaemia was confirmed by the appearance of regional myocardial surface cyanosis distal to the snare, and akinesia or bulging in this area. Experiments where these changes did not occur were discarded ($n=8$). After 15 min, the snare was released and reperfusion begun for a period of 2 h. Reperfusion was confirmed by changes in the pressure–length loop (increase in systolic shortening, reductions in post-systolic shortening and systolic bulging). Visually, reperfusion was confirmed by the appearance of hyperaemia. Animals that did not exhibit return of flow and change in ischaemic loop shape were excluded ($n=5$).

Measurements consisted of (1) steady state, and (2) caval occlusion obtained by pulling on the rubber tubing around the vena cava. Steady state variables were recorded for 5 s and caval occlusion for 15 s. All measurements were taken during expiratory apnoea to obtain an identical respiratory phase.

Nicorandil was dissolved in NaCl 0.9% (w/v). The dissolved nicorandil was infused in the marginal ear vein using an infusion pump.

DATA COLLECTION

ECG, pressures (central ear artery, left ventricular) and regional dimension signals were converted using an analogue-to-digital converter (AT-MIO-16, National Instruments Corporation, Austin TX, USA), and displayed continuously on an IBM AT personal computer using the real-time mode of software designed in this department. Data were sampled at a frequency of 500 Hz and stored on the hard disk. Pressure–length loops were displayed continuously on an oscilloscope.

DATA ANALYSIS

Data analysis was performed on an IBM AT personal computer using the play back mode of the above mentioned software. Peak positive and peak negative left ventricular dP/dt were obtained by electronic differentiation of the left ventricular pressure signal. End-diastole was defined as the first upward (positive) deflection of the left ventricular dP/dt signal. End-systole was defined as occurring at peak negative dP/dt.[12]

Length measurements were normalized to an initial value of end-diastolic length of 10 mm at control. The following definitions were used to quantify regional wall motion: EDL=end-diastolic length; ESL=end-systolic length; *l*max=maximum length during systole; *l*min=minimum segmental length during diastole. Systolic shortening fraction (%SS), systolic bulging (%SB) and post-systolic shortening (%PSS) were defined as follows:

$$\%SS = (EDL-ESL)/EDL \times 100$$
$$\%SB = (l\text{max}-EDL)/EDL \times 100$$
$$\%PSS = (ESL-l\text{min})/ESL \times 100$$

Systolic shortening was expressed in absolute values and as a percentage of pre-occlusion values to assess functional recovery during reperfusion. Area under the curve of systolic shortening *vs* time was also calculated during the reperfusion period.

Preload recruitable work area (PRWA) was calculated from the method devised by Glower and colleagues[13]; segmental stroke work (SW) was calculated by electronic integration of left ventricular pressure (P) and segmental length over the entire cardiac cycle:

$$SW = \int P \times dl$$

SW and end-diastolic segment length (EDL) were fitted using linear regression to the equation:

$$SW = Msw\ (EDL - Lw)$$

where Msw=slope and Lw=x-intercept.

PRWA was calculated from the equation:

$$PRWA = \frac{Msw}{2}(1.2Lwmax - Lw)^2$$

where Lwmax=maximal x-intercept value obtained for a given myocardial segment over the entire experiment.

PRWA was used to assess left ventricular function during the reperfusion period; values are expressed as a percentage of the pre-occlusion value. Area under the curve of PRWA *vs* time was also calculated during reperfusion.

STATISTICAL ANALYSIS

All values are expressed as mean (SEM). Statistical analyses were performed using two-way analysis of variance (ANOVA) with repeated measures on one factor. If ANOVA indicated significant differences between means, further comparisons were performed using Fisher's test. Statistical significance was assumed if $P<0.05$. Within-group comparisons were performed at times before ischaemia. Area under the curve and metabolic assays were analysed using one-way ANOVA followed by Fisher's test where appropriate.

Results

Of the 73 rabbits included in this study, 33 did not complete the experiment for the following reasons: death during surgery ($n=4$), crystals out of ischaemic area ($n=8$), lack of reperfusion after releasing the coronary snare ($n=5$), lethal ventricular fibrillation ($n=3$ in group F, $n=4$ in group I, $n=5$ in group FN and $n=4$ in group IN). Therefore, there were 10 animals in each group.

EFFECTS OF NICORANDIL OR ISOFLURANE, OR BOTH, BEFORE ISCHAEMIA

Isoflurane decreased left ventricular systolic pressure (LVSP) (73 (2) to 51 (1) mm Hg) while heart rate remained unchanged. Both $+dP/dt$max and $-dP/dt$min decreased with isoflurane suggesting a decrease in global contractility and lusitropy (table 1). Regional contractility was depressed in both groups receiving isoflurane, as indicated by the decrease in systolic shortening (27.3 (2.0) to 22.0 (1.4) % in group I and 28.7 (2.0) to 21.1 (1.8) % in group IN) and the slope of preload recruitable stroke work (Msw) (79.9 (11.1) to 42.7 (5.2) mm Hg in group I and 77.7 (10.4) to 43.0 (5.9) mm Hg in group IN) (table 2). Nicorandil infusion increased

+d*P*/d*t*max in group FN (3276 (293) to 3835 (307) mm Hg s^{-1}). EDL and EDP remained unchanged with isoflurane or nicorandil, or both.

EFFECTS OF NICORANDIL OR ISOFLURANE, OR BOTH, AFTER ISCHAEMIA

Both groups receiving isoflurane exhibited lower LVSP, +d*P*/d*t*max and −d*P*/d*t*min than both groups receiving fentanyl. Nicorandil did not affect these variables (table 1). Table 2 shows the changes in systolic shortening expressed as absolute values; group FN displayed higher values than the three other groups, however, this group displayed higher pre-occlusion values than groups I and IN. Systolic shortening normalized to the pre-occlusion value exhibited higher values in both groups receiving nicorandil (fig. 4). This was confirmed by the area under the curve (table 3). PRWA (fig. 5) showed similar trends, but at variance with the previous indices there were significant differences between groups IN and FN (99.3 (10.5) and 73.4 (7.5) %, respectively, at 120 min reperfusion). This was confirmed by the area under the curve (table 3). The differences between groups became more obvious after 30 min of reperfusion.

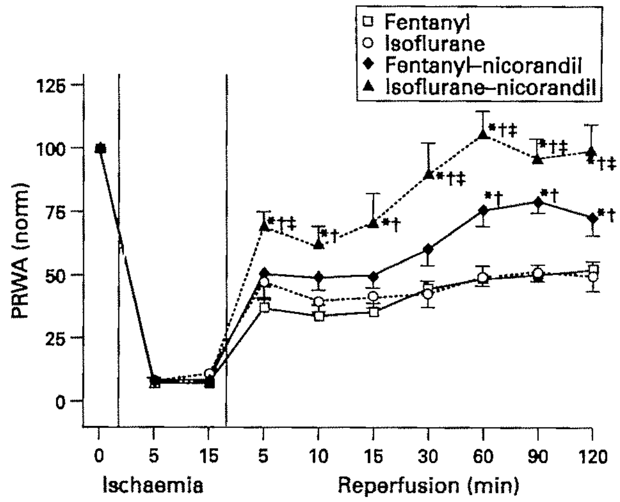

Figure 5 Changes in preload recruitable work area (PRWA) normalized to pre-occlusion values during and after ischaemia for the four groups. *$P<0.05$ compared with fentanyl group, †$P<0.05$ compared with isoflurane group, ‡$P<0.05$ compared with fentanyl–nicorandil group.

BIOCHEMICAL ANALYSIS

Tissue ATP concentrations were similar between groups; however ATP concentrations were decreased significantly in reperfused tissue (previously ischaemic region) compared with non-ischaemic areas in each group. Lactate and energy charge were not different between groups or within regions (table 4).

Table 4 ATP, lactate and energy charge levels in reperfused and non-ischaemic tissue (μmol g^{-1} wet weight). F=Fentanyl group, I=isoflurane group, FN=fentanyl and nicorandil group and IN=isoflurane and nicorandil group. *$P<0.05$ compared with non-ischaemic tissue

Discussion

K_{ATP} channels are present in several tissues, including cardiac muscle and vascular smooth muscle. Their gating is metabolically dependent; a decrease in intracellular ATP or increase in ADP or protons may induce a K^+ outward current which hyperpolarizes the cell. Glibenclamide, a K_{ATP} channel blocker, increases basal coronary tone, suggesting that K_{ATP} channels play an important physiological role in coronary vasoregulation.[14] K_{ATP} channels have also been implicated in the cardioprotection produced by agents such as nicorandil[15] and isoflurane.[6 16]

Nicorandil is a K_{ATP} channel opener; it induces vasodilatation because of cell membrane hyperpolarization resulting in decreased calcium entry through T- and L-type calcium channels. Vasodilatation is also attributed to the presence of a nitrate radical. Small artery dilatation seems to be mediated by a K_{ATP} channel opening action and large artery dilatation mediated by a nitrate-like effect.[17] Experimental studies in dogs[18] have shown that nicorandil enhances cardiac function. This could be attributed to altered loading status,[19] increased coronary flow, or both.[20]

Isoflurane causes dose-related vasodilatation. Patch clamp studies have shown that it acts by suppressing calcium currents.[21] Recently, Cason, Shubayev and Hickey[5] demonstrated that isoflurane-induced coronary vasodilatation *in vivo* is antagonized by the K_{ATP} channel blocker glibenclamide and concluded that this vascular effect is mediated mainly by K_{ATP} channel modulation; similar results have been obtained with halothane.[22] To our knowledge, only one study has investigated the potential haemodynamic effects of the combination of nicorandil and isoflurane: Tanaka,[23] using 0.75% and 1.5% isoflurane in an open chest anaesthetized dog model investigated the global haemodynamic effects of bolus doses of nicorandil 100 $\mu g\ kg^{-1}$ and 300 $\mu g\ kg^{-1}$. They showed that the hypotensive effects of both nicorandil doses disappeared after 5 min at both isoflurane concentrations. Cardiac output was slightly increased during the first minute at both doses, as there was a transient decrease in vascular resistance.

The cardiodepressant properties of isoflurane are mediated by inhibition of trans-sarcolemmal calcium influx by T- and L-calcium voltage-dependent channels.[24] This results in decreased calcium availability for myocardial contraction. Contractile myofibrils also exhibit decreased calcium sensitivity. Compared with other halogenated anaesthetics, isoflurane seems to have less effect on the sarcoplasmic reticulum. In this study, isoflurane was set at 1 MAC (rabbit) end-tidal concentration, equivalent to 2.05%,[11] a dose that causes marked hypotension and cardiodepression in this model.

In our model, nicorandil showed no hypotensive effects 15 min after the bolus dose of 100 $\mu g\ kg^{-1}$ and continuous infusion of 25 $\mu g\ kg^{-1}\ min^{-1}$, with fentanyl or isoflurane anaesthesia. However, $+dP/dt$max was increased significantly after administration of nicorandil with fentanyl but not isoflurane anaesthesia, possibly because of the magnitude of induced vasodilatation and cardiodepression with isoflurane. Using a model similar to ours, Iwamoto and colleagues[15] showed a cardioprotective effect without hypotensive action with infusion of nicorandil 10 $\mu g\ kg^{-1}\ min^{-1}$.

Mechanisms underlying transient post-ischaemic myocardial dysfunction are still not fully understood. The more favoured causes are cytosolic calcium overloading ("calcium paradox"), formation of free radicals during reperfusion and decrease in myofibril sensitivity to calcium. During ischaemia, intracellular ATP decreases and ADP, lactate and acidosis increase in the cardiac myocyte. These intracellular metabolic alterations induce efflux of potassium ions through K_{ATP} channels shortening action potential duration. Contractility in ischaemic myocardium is reduced and metabolic demand decreases. The protective effects of nicorandil on stunned myocardium have been studied extensively in a chronically instrumented dog model[25] and in a pentobarbitone-anaesthetized open chest dog model.[2 3] These studies on stunned myocardium used similar doses of nicorandil as in this study. In these investigations myocardial function was assessed by regional systolic shortening (SS%). Several studies have also reported a decrease in infarct area after longer periods of ischaemia using nicorandil. The cardioprotective effect has been attributed to the dual properties of nicorandil: potassium channel opener[2] and vasodilator,[26] although the role of the latter is still debated. Compared with equi-hypotensive doses of nitrates, nicorandil showed improved recovery.[3] However, intracoronary infusion of nicorandil[26] and systemic infusion of aprikalim, a pure potassium channel opener, after ischaemia,[27] did not show a demonstrable beneficial effect. Other properties may be involved in the protective effect of nicorandil, including free radical scavenging activity[28] and antiplatelet aggregatory function.[29]

Halogenated anaesthetics also have cardioprotective properties. Both halothane and isoflurane have been shown to improve post-ischaemic recovery in several animal models[4 30–32] but the mechanisms remain unclear; decreased myocardial contractility and oxygen demand do not appear to play major roles.[33] Halogenated anaesthetics are more likely to exert their effects by decreasing the intracellular calcium transient, thereby protecting the heart against calcium overloading. The free radical scavenging properties of isoflurane[34 35] may also be involved. Kersten and colleagues[6] have recently shown that isoflurane-induced cardioprotection in stunning is partially blocked by glibenclamide in a chronic dog model, suggesting a role for K_{ATP} channels.

We have been unable to show a protective effect on myocardial recovery for isoflurane compared with fentanyl. The low perfusion pressure displayed by the groups receiving 1 MAC of isoflurane may have affected recovery, and coronary steal may have been induced,[36] although this phenomenon is still debated.[37] In our study, we demonstrated enhanced recovery from stunning in animals receiving both isoflurane and nicorandil. The group receiving isoflurane and nicorandil showed significant enhancement (+26%) in PRWA compared with the group receiving fentanyl and nicorandil. PRWA is a good index of systolic function in the post-ischaemic period; compared with systolic shortening, it is sensitive and relatively load independent.[13] By expressing contractility as systolic shortening in absolute values, the isoflurane and nicorandil group recovered less compared with the fentanyl and nicorandil group. This may be attributed to the cardiodepressive activity of isoflurane, as shown by the similar recovery when systolic shortening in the isoflurane group was normalized to a pre-occlusion value.

Our study demonstrated significant depletion in tissue ATP content in the previously ischaemic area in all groups; this was not, however, reflected in decreased energy charge in the same areas. Assessment of cellular energy status may include other indices not measured here, such as phosphorylation potential ([ATP]/[ADP]+Pi), phosphocreatine and glycogen contents. However, it is likely that turnover and flux rates of energy substrates and intermediary metabolites are more important than absolute concentrations. Another relevant factor in this context is compartmentation of metabolites between subcellular sites. Measurements of whole tissue concentrations cannot account for localization of energy substrates within different organelles. Indeed, it has been suggested that whole tissue myocardial ATP content is not related to functional recovery after ischaemia,[38 39] an observation confirmed by this report.

Tissue lactate concentrations were also unchanged after 2 h of reperfusion in all groups, confirming the metabolic integrity implied by the energy charge status and suggesting myocardial stunning with good biochemical recovery at 2 h of reperfusion rather than overt tissue infarction.

LIMITATIONS

Using this model we cannot state unequivocally if the differences in functional recovery were related to better functional recovery in stunned myocardium or to diminished infarct size. Weisel[40] suggested a time of 10–20 min for stunning in rabbits. We did not measure collateral circulation, but radiomicrosphere studies[41] have shown that collateral circulation in rabbits is poor (2%) compared with dogs (16%). This is one major advantage of using the rabbit model to study stunning. As we used an acute model, this study did not examine contractile function in reperfused areas after recovery from anaesthesia; a similar study with a chronic model would be necessary to establish the extent of recovery without anaesthesia. Our model did not allow us to measure coronary flow to determine if there was further enhancement of coronary flow with the combination of isoflurane and nicorandil, which may induce coronary steal. However, if this was the case recovery would be expected to be less in this group compared with the fentanyl and nicorandil group. Systolic pressures were very low in the isoflurane groups, however further experiments carried out in this department using 0.5 MAC of isoflurane have shown the same degree of contractile recovery with systolic pressures greater than 70 mm Hg (unpublished observations). Plasma concentrations of nicorandil were not measured, therefore we cannot be certain that plasma concentrations were stable during the experiment. Moreover, the cardiovascular system of the rabbit appears to be more sensitive to isoflurane. Consequently, caution must be exercised before relating this work to a clinical situation.

In summary, we have shown better recovery of stunned myocardium with the addition of nicorandil to isoflurane or fentanyl anaesthesia in acutely instrumented anaesthetized rabbits. The mechanisms underlying the benefits of the combination of isoflurane and nicorandil are unclear. Enhancement of the cardioprotection afforded by nicorandil and isoflurane may involve K_{ATP} channel opening.

Effect of halothane on K^+ and carbachol stimulated [^{3}H]noradrenaline release and increased $[Ca^{2+}]_i$ in SH-SY5Y human neuroblastoma cells

R. ATCHESON, K. BJORNSTROM, R. A. HIRST, D. J. ROWBOTHAM AND D. G. LAMBERT

Summary

We have examined the effects of the volatile general anaesthetic agent, halothane, on K^+ and carbachol stimulated [^{3}H]noradrenaline release and associated increases in intracellular Ca^{2+} in a cultured human neuroblastoma cell line, SH-SY5Y. K^+ (but not carbachol) stimulated [^{3}H]noradrenaline release, and the increase in intracellular Ca^{2+} concentration was entirely extracellular Ca^{2+} dependent. Halothane produced a dose-dependent reduction in K^+ evoked release of [^{3}H]noradrenaline with significant inhibition (17%) occurring from 1.26 atm%. Basal and carbachol evoked release were unaffected. Halothane also produced a dose-dependent reduction in K^+ evoked increases (measured at the peak) in intracellular Ca^{2+} with significant inhibition (29%) occurring from 0.88 atm%. K^+ plateau, basal and carbachol evoked increases in intracellular Ca^{2+} were unaffected. These data suggest that halothane reduced Ca^{2+} entry through voltage-sensitive Ca^{2+} channels and implicate this important class of ion channel in the mechanism of anaesthesia. (*Br. J. Anaesth.* 1997; **79**: 78–83).

Key words
Anaesthetics volatile, halothane. Ions, ion channels, voltage-gated. Ions, calcium. Sympathetic nervous system, noradrenaline. Model, neuroblastoma cells. Theories of anaesthetic action, molecular.

Neurophysiological studies suggest that anaesthetic agents depress synaptic transmission by reducing neurotransmitter release with axonal conduction remaining relatively unaffected.[1–3] While there is good agreement that neurotransmission is reduced, the precise cellular mechanism(s) remains to be fully elucidated. At clinically relevant concentrations, anaesthetic agents (with the exception of ketamine) interact with $GABA_A$ receptors to increase Cl^- conductance and produce hyperpolarization, suggesting that this may be a common target site for all anaesthetic agents.[4,5] However, at variance with this hypothesis is the observation that some anaesthetics *inhibit* the release of GABA.[6,7] While the GABA hypothesis is extremely attractive, it is premature to discount other potential target site(s). One such target is the voltage-sensitive Ca^{2+} channel and there has been much debate as to its importance in general anaesthesia.[5,8,9] As the presynaptic regulation of neurotransmitter release is, in general, a Ca^{2+}-dependent process,[10] closing of presynaptic voltage-sensitive Ca^{2+} channels seems a logical mechanism for inhibition of transmitter release. Such a mechanism (with hyperpolarization) is used by opioid receptors.[11,12]

We have demonstrated previously that release of [^{3}H]noradrenaline from SH-SY5Y cells in response to K^+ and carbachol stimulation uses different sources of Ca^{2+}.[13] For K^+ the response is extracellular Ca^{2+} dependent whereas for carbachol the response in extracellular Ca^{2+} independent.[13] Purkiss, Nahorski and Willars have also demonstrated in this cell line that muscarinic stimulation of release used Ca^{2+} from the inositol (1,4,5) triphosphate ($Ins(1,4,5)P_3$) sensitive store[14] and muscarinic receptor stimulation is known to produce a substantial biphasic increase in $Ins(1,4,5)P_3$ mass in these cells.[15,16] While we are not claiming that the release of noradrenaline *per se* is involved in the anaesthetic state we have used the well defined characteristics of the release process to probe the site(s) of action of a range of anaesthetics, including thiopentone, propofol[17] and ketamine.[18] In this study using SH-SY5Y cells, we report that the volatile general anaesthetic agent, halothane, selectively inhibited K^+ evoked noradrenaline release suggesting that this agent inhibited Ca^{2+} entry through voltage-sensitive Ca^{2+} channels.

Materials and methods

CELL CULTURE AND BUFFERS

SH-SY5Y cells, passages 70–90, were maintained in minimum essential medium supplemented with penicillin 100 u. ml^{-1}, streptomycin 100 μg ml^{-1}, fungizone 2.5 μg ml^{-1} and 10% fetal calf serum.

Stock cultures were passaged weekly and re-fed twice weekly. All experiments were performed in suspensions of cells that were harvested from confluent flasks by brief exposure to HEPES (20 mmol litre^{-1}) buffered saline (0.9%) containing EDTA (0.02%). All cells were resuspended in Krebs/HEPES buffer, pH 7.4, of the following composition (mmol litre^{-1}): Na^+ 143.3, K^+ 4.7, Ca^{2+} 2.5, Mg^{2+} 1.2, Cl^- 125.6, $H_2PO_4^{2-}$ 1.2, SO_4^{2-} 1.2, glucose 11.7 and HEPES 10. In K^+ depolarization studies, buffer Na^+ was adjusted accordingly.

[^{3}H]NORADRENALINE RELEASE

Suspensions of SH-SY5Y cells were loaded with [^{3}H]noradrenaline as described previously.[13 19] Briefly, cells were incubated with [^{3}H]noradrenaline (approximately 40 nmol litre^{-1}, 41 Ci mmol^{-1}, Amersham Bucks, UK) for 1 h at 37 °C. Loaded cells were centrifuged, resuspended in 1 ml of fresh buffer and incubated for 15 min. This procedure was repeated. Cells were then loaded into the perfusion chamber[13] and perfused at 0.5 ml min^{-1} for 15 min. For K^+ stimulation, cells were perfused with K^+ (S_1, 100 mmol litre^{-1}) for 3 min, then after 15 min were rechallenged with K^+ (S_2, 100 mmol litre^{-1}, 3 min). For muscarinic receptor stimulation experiments, the perfusion regimen was the same as that for K^+ except that cells were perfused with a single pulse of carbachol (1 mmol litre^{-1}, 3 min) in order to avoid receptor-mediated desensitization.

[^{3}H]Noradrenaline was measured in fractions (0.25 ml) of perfusate collected at 30-s intervals. Scintillation cocktail (Optipase Safe, 4 ml) was added to each fraction and the amount of [^{3}H]noradrenaline determined by scintillation spectrophotometry.

Halothane was delivered to the buffer reservoir using a pre-calibrated Fluotec agent specific vaporizer with humidified air as the carrier gas. The humidifier was positioned after the vaporizer. Vaporizer settings of 1–5 atm% were used (in random order) and air was the control. Halothane was perfused from saturated solutions for 15 min either between S_1 and S_2 (for K^+) or during the final 15-min buffer perfusion (for carbachol). Aqueous halothane concentrations were measured in both the reservoir and at the perfusion chamber outlet (see below).

MEASUREMENT OF INTRACELLULAR CALCIUM CONCENTRATION ([CA^{2+}]$_i$)

[Ca^{2+}]$_i$ was measured fluorimetrically using a Perkin-Elmer LS50B fluorimeter with excitation wavelengths set at 340 and 380 nm; emission was measured at 510 nm. SH-SY5Y cell suspensions were incubated with Fura2AM 3 µmol litre^{-1} for 30 min at 37 °C and then post-incubated with fresh buffer for another 20 min at room temperature to allow for complete ester hydrolysis.[20] Loaded cells (200 µl) were placed into a cuvette containing 1.8 ml of buffer, pre-equilibrated for 15 min with halothane (vaporizer setting 0.75, 1.5 and 3.0 atm% in random order) via "surface blowing". After another 3 min of gassing, the cells were exposed to either K^+ 80 mmol litre^{-1} or carbachol 1 mmol litre^{-1} in the continued presence of halothane or air. Excitation ratio measurements (340/380) were obtained every 1 s and converted to [Ca^{2+}]$_i$ according to Grynkiewicz, Poenie and Tsien[21] where maximum (Rmax) and minimum (Rmin) fluorescence ratios were estimated using 0.1% Triton X and EGTA 4.5 mmol litre^{-1}, respectively. Halothane did not affect the fluorescence properties of Fura2. Aqueous halothane concentrations were measured in the cuvette (see below).

MEASUREMENT OF AQUEOUS HALOTHANE CONCENTRATIONS

Buffer halothane concentrations were measured by gas chromatography according to Rutledge and colleagues.[22] After equilibration for various times at various vaporizer settings, 100 µl of buffer was injected rapidly to sealed glass vials containing

Table 1 Aqueous halothane concentrations in [^{3}H]noradrenaline release (A) and [Ca^{2+}]$_i$ (B) experiments measured at 37 °C. Data are mean (SEM) from at least five determinations. Equivalent atm% is calculated assuming 1 atm% at 37 °C and at equilibrium with the aqueous phase gives 280 µmol litre^{-1} [23]

100 µl of heptane; 1.5 µl of the upper phase (containing halothane) was then injected onto the column. Sample integrated peak heights were compared with halothane standards made up on ice in heptane. Aqueous halothane concentrations are shown in table 1 and indicate that 15 min of "gassing" in either experimental regimen was sufficient to attain equilibrium with the aqueous phase. However, in [^{3}H]noradrenaline release experiments, halothane was lost (approximately 40%) in the perfusion system. The same perfusion chamber and pipework were therefore used throughout and the aqueous concentration taken as that at the chamber. In all subsequent data, halothane concentration refers to measured atm%.

DATA ANALYSIS

Data are presented as mean (SEM). To control for differing numbers of cells in the perfusion chamber in [^{3}H]noradrenaline experiments, release is expressed relative to the first fraction collected. Area under the normalized curves (AUC) was calculated and S_2/S_1 ratios estimated for K^+. For carbachol, the single pulse AUC was compared with control. Where appropriate data were analysed using ANOVA or Student's paired *t* test, or both.

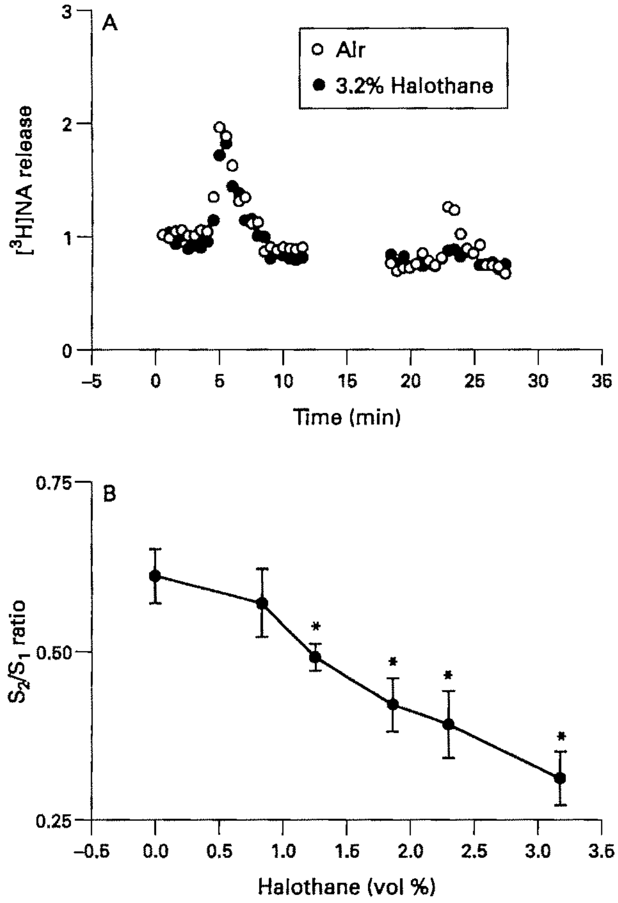

Figure 1 Halothane inhibited K^+ evoked [^{3}H]noradrenaline (NA) release from perfused SH-SY5Y human neuroblastoma cells. A: Release profile to two 3-min pulses (S_1 and S_2) of K^+ 100 mmol litre^{-1} (single experiment from n=5). To control for varying numbers of cells in the chambers, data are expressed relative to the first fraction collected. The area under the normalized curves were estimated and S_2/S_1 ratios calculated. Dose-dependent reduction in S_2/S_1 ratio is presented in (B) from mean (SEM) of n=5–7. Whole curve $P<0.05$ by ANOVA and *$P<0.05$ compared with 0% halothane (air).

Table 2 Effects of halothane on carbachol evoked [^{3}H]noradrenaline release (A) and increase in $[Ca^{2+}]_i$ (B). All data are mean (SEM). No significant differences between groups

Results

Both K^+ 100 mmol litre^{-1} (fig. 1A) and carbachol 1 mmol litre^{-1} (data not shown) produced a monophasic increase in the release of [^{3}H]noradrenaline from undifferentiated SH-SY5Y human neuroblastoma cells. For K^+ a second monophasic release profile could be elicited 15 min after the first challenge with K^+, yielding an S_2/S_1 ratio of 0.61 (0.04) (n=7). When applied between S_1 and S_2, halothane produced dose-dependent inhibition of S_2 (fig. 1A) and hence S_2/S_1 ratio (fig. 1B). As maximum inhibition was not achieved, we could not estimate an IC_{50} value but significant ($P<0.05$) inhibition (17%) occurred at 1.26 atm% (approximately 1.5 MAC). Halothane did not affect basal (data not shown, n=2) or carbachol evoked [^{3}H]noradrenaline release (table 2).

Both K^+ 80 mmol litre^{-1} (fig. 2A) and carbachol 1 mmol litre^{-1} (data not shown) produced a biphasic increase in $[Ca^{2+}]_i$. For K^+ the peak value was 196 (11) nmol litre^{-1} and the plateau level (2 min after stimulus) was 122 (14) nmol litre^{-1}. Corresponding values for carbachol were 543 (56) nmol litre^{-1} and 204 (12) nmol litre^{-1}, respectively. After a 15-min equilibration period, halothane produced a dose-dependent inhibition of the K^+ peak increase in $[Ca^{2+}]_i$ (fig. 2). As maximum inhibition was not achieved, we could not estimate an IC_{50} value but significant inhibition (29%) occurred at 0.88 atm% (approximately 1.2 MAC). Basal, plateau (fig. 2) and carbachol (table 2) evoked increases in $[Ca^{2+}]_i$ were unaffected by halothane.

Discussion

We have demonstrated that the volatile general anaesthetic halothane produced a dose-dependent

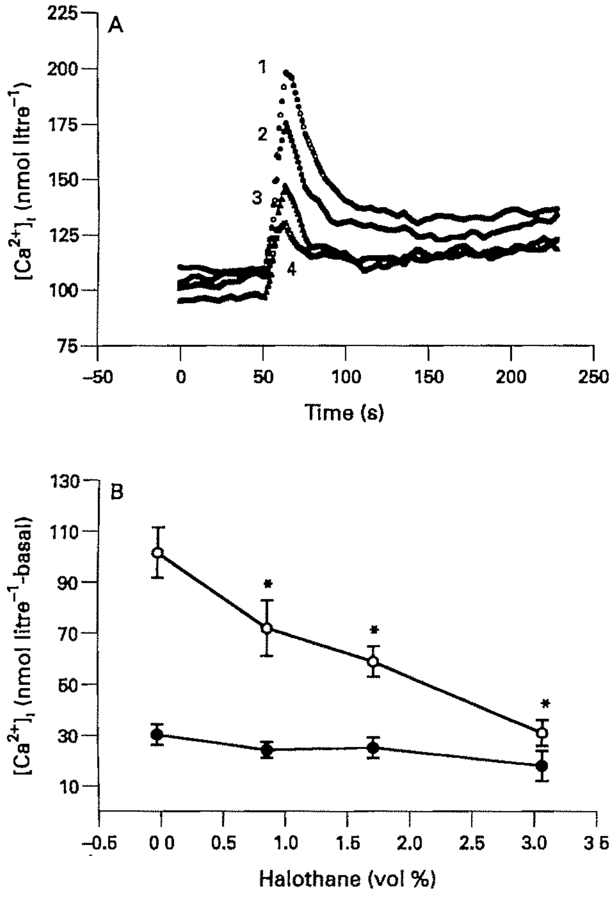

Figure 2 Halothane reduced peak but not plateau phase increase in $[Ca^{2+}]_i$ in Fura2 loaded SH-SY5Y human neuroblastoma cells after stimulation with K^+ 80 mmol litre^{-1}. A: Time course to K^+ 80 mmol litre^{-1} challenge for air control (1), 0.88% (2), 1.73% (3) and 3.08% (4) halothane, data from a single representative experiment. Basal levels of $[Ca^{2+}]_i$ (air 94 (6) nmol litre^{-1}, *n*=13; 0.88 atm% 106 (9) nmol litre^{-1}, *n*=11; 1.73 atm% 98 (5) nmol litre^{-1}, *n*=12; 3.00 atm% 100 (5) nmol litre^{-1}, *n*=12) were unaffected by halothane. The dose–response curve for peak (○) and plateau (●) phase is shown in (B), after subtraction of a variable basal. Data are mean (SEM) from *n*=6–8. The peak phase curve was $P<0.05$ by ANOVA and all concentrations were reduced significantly ($^*P<0.05$) compared with 0% halothane (air).

inhibition of K^+ but not carbachol evoked [^{3}H]noradrenaline release from SH-SY5Y human neuroblastoma cells. As K^+ (but not carbachol) evoked release is extracellular Ca^{2+} dependent[13] these data suggest that halothane inhibited Ca^{2+} entry through voltage-sensitive Ca^{2+} channels. Indeed, further studies in Fura2 loaded SH-SY5Y cells showed dose-dependent inhibition of K^+ but not carbachol evoked increase in intracellular Ca^{2+}. This indicates that halothane reduced voltage-sensitive calcium channel (VSCC) gated Ca^{2+} influx in these cells resulting in reduced [^{3}H]noradrenaline release. Moreover, the concentrations required to achieve significant inhibition (1.26 atm% and 0.88 atm% for [^{3}H]noradrenaline release and increased intracellular Ca^{2+}, respectively) agree well with clinically relevant concentrations for this agent.[23] A clinical estimate of IC_{50} is the minimum alveolar concentration (MAC) of agent that inhibits movement to skin incision in 50% of patients; for halothane this is 0.75 atm%.[23] However, while this value agrees well with our data for significant inhibition, extrapolation of MAC (for a whole organism) to measurements made with isolated neuronal cells is difficult, and should be undertaken carefully.

In SH-SY5Y cells, depolarization with high doses of K^+ produces an increase in Ca^{2+} influx through both L- and N-type voltage-sensitive Ca^{2+} channels measured in Fura2 loaded cells.[24] In addition, the existence of these channels has been demonstrated electrophysiologically, although L channels are likely to be expressed at low levels.[25] Indeed, we have noted that SH-SY5Y cells express low levels of L-type VSCC (<10 fmol/mg protein [^{3}H]PN200-110 binding sites[26]). This study gives no indication of which channel (L, N or both) is inhibited by halothane. For carbachol, the increase in intracellular Ca^{2+} was biphasic with the peak phase representing release of Ca^{2+} from an $Ins(1,4,5)P_3$ sensitive store and the plateau phase representing Ca^{2+} influx through a receptor operated Ca^{2+} channel.[27 28] The time course for generation of $Ins(1,4,5)P_3$ was also biphasic showing a close temporal (and dose) relationship.[15 16] Our data clearly showed that muscarinic agonist increased intracellular [Ca^{2+}] and the subsequent increased [^{3}H]noradrenaline release was relatively unaffected by halothane.

Volatile anaesthetics have been shown to inhibit the release of a variety of neurotransmitters from various tissues.[2] Halothane inhibits the release of catecholamines from bovine adrenal chromaffin cells at clinically relevant concentrations in response to carbachol (presumably acting at nicotinic receptors in this preparation) but not depolarization.[29 30] Similar findings have also been reported for enflurane, isoflurane and methoxyflurane.[30] In our study we found the opposite effect, with K^+ but not carbachol evoked release being reduced. This may result from muscarinic M_3 receptors coupling to release in SH-SY5Y cells and nicotinic receptors coupling to release in chromaffin cells. However, it should also be noted that some batches of SH-SY5Y cells express nicotinic receptors and nicotine has been shown to increase intracellular Ca^{2+} and stimulate [^{3}H]noradrenaline release.[31 32] However, in our hands nicotinic receptor stimulation did not produce significant depolarization or Ca^{2+} entry.[33] Bazil and Minneman[34] and Mantz and colleagues[35] reported in rat cerebrocortical slices and rat striatal synaptosomes that halothane reduced depolarization evoked catecholamine release at clinically relevant concentrations. Interestingly, in the former study [^{3}H]acetylcholine release was unaffected.[34] Halothane and isoflurane inhibited K^+ evoked catecholamine secretion and increase in intracellular Ca^{2+} through L-type VSCC from PC12 cells at clinically relevant concentrations.[36] In addition to these reported inhibitory effects of volatile anaesthetics, stimulatory effects have also been reported; for example, halothane, enflurane, isoflurane and methoxyflurane enhanced phorbol ester evoked catecholamine release from PC12 cells.[37]

Volatile anaesthetic agents have been shown to affect intracellular Ca^{2+} in many cell types.[9 36] Both inhibitory and stimulatory effects have been observed, with volatile agents inhibiting Ca^{2+} entry through a variety of channels,[29 38 39] promoting release from intracellular (caffeine, ryanodine and $Ins(1,4,5)P_3$ sensitive) Ca^{2+} stores[41 42 44] and inhibiting release of Ca^{2+} from intracellular stores.[43 44] However, while there are many studies of the effects of volatile agents on Ca^{2+} homeostasis, the role of this divalent cation in the mechanisms of general anaesthesia still remains controversial, especially with respect to VSCC activity.[5 8 9] In addition, the potency of halothane for the production of anaesthesia in humans displays a steep curve, with MAC=0.75 atm%,[5] whereas inhibition of VSCC in this study showed a more shallow curve. We feel that the comparison of dose-related effects of halothane on VSCC activity with estimation of MAC in a population of subjects should be made with caution. While inhibition of Ca^{2+} entry in K^+ depolarized SH-SY5Y cells reported here (and subsequent inhibition of $[^3H]$noradrenaline release) is in general agreement with the studies noted above, the insensitivity of carbachol stimulated increase in intracellular Ca^{2+} is worthy of special note. Others have reported that agonist (non-depolarizing) stimulated increases in intracellular Ca^{2+} can be reduced by volatile general anaesthetics, for example in GH_3 pituitary cells, receptor operated Ca^{2+} channel activity is blocked by halothane.[45] There are few reports of the effects of volatile anaesthetic agents on phosphoinositide hydrolysis.[46 47] We have measured $Ins(1,4,5)P_3$ mass formation in response to halothane and isoflurane in SH-SY5Y cells and reported dose-dependent (EC_{50} for halothane at 0.75 atm%) enhancement of carbachol stimulated $Ins(1,4,5)P_3$ formation.[47] In addition, basal $Ins(1,4,5)P_3$ formation was also enhanced. These data are at variance with the lack of effect of halothane on basal or carbachol stimulated increase in intracellular Ca^{2+} and $[^3H]$noradrenaline release. However, the increase in $Ins(1,4,5)P_3$ formation was relatively small in comparison with the increase produced by carbachol.

In summary, we have shown that halothane, at concentrations which produce general anaesthesia, inhibited depolarization (but not muscarinic agonist) evoked release of $[^3H]$noradrenaline by reducing Ca^{2+} influx through VSCC. These data are in general agreement with our previous findings for propofol, thiopentone[17] and ketamine[18] and adds weight to our hypothesis that VSCC may be a target site for anaesthetic agents. Clearly, this hypothesis will need further rigorous testing.

Role of endothelium in the modulation of isoflurane-induced vasodilatation in rat thoracic aorta

P. KIRSTETTER, F. LAGNEAU, O. LUCAS, Y. KRUPA AND J. MARTY

Summary

The mechanisms by which endothelium attenuates vasodilatation caused by isoflurane are not well understood. We examined the role of endothelium-derived substances, nitric oxide (NO), endothelium-derived hyperpolarizing factors (EDHF), prostanoids and endothelins in the response to isoflurane in rat thoracic aorta. Increasing cumulative concentrations of isoflurane were administered to aortic rings suspended in Hepes solution and preconstricted with either phenylephrine 10^{-6} mol litre^{-1} or KCl 40 mmol litre^{-1} (which inhibit EDHF). Rings were intact, denuded or incubated with an inhibitor of nitric oxide synthesis (Nω-nitro-L-arginine (LNNA 5×10^{-5} mol litre^{-1}), an inhibitor of prostanoid synthesis (indomethacin 10^{-5} mol litre^{-1}) or a blocker of the vascular receptors to endothelins (cyclo (-D-trp-D-Asp-Pro-D-Val-Leu (BQ 123 10^{-5} mol litre^{-1})). Endothelium attenuated isoflurane-induced vasodilatation in KCl-constricted rings at concentrations of 4% (mean 95 (SEM 4) % *vs* 72 (4) %; $P=0.0005$) and 5% (100 (4) % *vs* 80 (4) %; $P=0.0008$) and in phenylephrine constricted rings at concentrations of 4% (54 (8) % *vs* 35 (3) %; $P=0.04$) and 5% (78 (10) % *vs* 49 (5) %; $P=0.03$). Relaxation was significantly greater in rings treated with LNNA than in intact rings at concentrations of 4% (85 (4) % *vs* 72 (4) %; $P=0.0005$) and 5% (90 (4) % *vs* 80 (4) %; $P=0.0008$). Indomethacin and BQ 123 did not alter isoflurane-induced vasodilatation. We conclude that endothelium attenuated the vasodilator effect of isoflurane by a mechanism which was abolished by inhibition of nitric oxide. We hypothesize that isoflurane inhibits the release of nitric oxide, leading to a relative vasoconstriction counterbalancing its vasodilator effect. In contrast, EDHF, prostanoids and endothelins were not involved in the attenuation of isoflurane-induced vasodilatation. (*Br. J. Anaesth.* 1997; **79**: 84–87).

Key words
Anaesthetics volatile, isoflurane. Muscle vascular, responses. Pharmacology, nitric oxide. Rat.

Isoflurane is a volatile anaesthetic which relaxes vascular smooth muscle cells.[1–7] It has been shown previously that vessels without endothelium relaxed more than vessels with endothelium,[4,7] suggesting that isoflurane may either decrease the release of endothelium-derived relaxing factors or increase the release of endothelium-derived contracting factors. A previous study examined the role of nitric oxide (an endothelium-derived relaxing factor) and found that relaxation was comparable between denuded vessels and vessels treated with an inhibitor of nitric oxide synthase.[7] It has also been shown that the release of nitric oxide was decreased by volatile anaesthetics[8–15] suggesting that nitric oxide accounts for the lesser degree of relaxation obtained in intact vessels compared with denuded vessels.

Even if nitric oxide is responsible for this effect, isoflurane may also inhibit the release of other endothelium-derived vasodilators (i.e. prostacyclin and endothelium-derived hyperpolarizing factors (EDHF)) or may increase the release of endothelium-derived vasoconstrictors (i.e. endothelins and thromboxane A_2). It has been shown recently that prostanoids and EDHF were decreased by isoflurane,[16,17] but their role in modulating the action of volatile anaesthetics on the intact vessel has not been investigated. In addition, interactions between isoflurane and release of endothelins by vessels have not been examined.

The aim of this study was to examine the role of nitric oxide, prostanoids, EDHF and endothelins in the modulation of relaxation induced by isoflurane in isolated rat thoracic aorta.

Materials and methods

ANIMALS

We used male Sprague–Dawley rats (300–350 g) (Iffa-Credo, France). The study was approved by the French Agriculture Office in conformity with European Legislation Involving Animals.

PREPARATION OF AORTIC RINGS

Animals were anaesthetized with pentobarbitone 50 mg kg^{-1} i.p., which does not alter the reactivity of vessels removed from these animals.[18] The thoracic aorta was removed and placed in modified Hepes buffer (37 °C) aerated with a mixture of 95% oxygen and 5% carbon dioxide. Aorta were dissected clean of fat and extraneous tissues and divided into 3.5–4.0-mm ring segments. In some rings, endothelium was removed mechanically by gently rubbing the intimal surface with a stainless steel rod. The rings were suspended between two L-shaped stainless steel hooks and placed in a 10-ml, water-jacketed organ chamber containing a solution composed of (mmol $litre^{-1}$) NaCl 118.2, KCl 4.7, $NaHCO_3$ 25.0, KH_2PO_4 1.2, $MgSO_4$ 1.2, $CaCl_2$ 2.5, glucose 11.1 and Hepes 5. Organ chambers were aerated continuously with 95% oxygen and 5% carbon dioxide with pH maintained at 7.35–7.40.[19] Temperature was maintained constant at 37 °C. Isometric tensions were measured (g) using a force displacement transducer (UF1 Pioden Controls, Paris, France) connected to the upper hook. Tensions were recorded on a Servo trace recorder (Sefram, Paris). During the equilibration period of 60 min, the buffer was changed every 15 min and resting tension was adjusted periodically to 1.5 g. Active contraction was induced with KCl 40 mmol $litre^{-1}$ and the integrity of endothelium was assessed by testing the relaxation produced by the addition of acetylcholine 10^{-6} mol $litre^{-1}$.[20] Endothelium was considered intact when acetylcholine elicited a minimum of 30% vasodilatation. Endothelium was considered removed when acetylcholine induced no vasodilatation. After acetylcholine testing, the rings were washed and re-equilibrated to baseline tension for 60 min. After this new period of stability, rings were constricted with KCl 40 mmol $litre^{-1}$ or phenylephrine 10^{-6} mol $litre^{-1}$. Isoflurane was then delivered using a calibrated agent-specific vaporizer (Abbott, France). The concentrations of isoflurane in the gas phase were monitored and adjusted using an anaesthetic agent monitor. Aortic rings were exposed to cumulative concentrations of isoflurane of 1–5%. Each concentrations was maintained until the effect on the aortic ring reached a plateau (i.e. an average of 10 min). The vasodilator effect of isoflurane was expressed as percentage decrease in tension compared with the plateau reached after KCl or phenylephrine.

ROLE OF ENDOTHELIUM AND ENDOTHELIUM-DERIVED NITRIC OXIDE, PROSTANOIDS, EDHF AND ENDOTHELINS IN ISOFLURANE-INDUCED VASODILATATION

The role of endothelium was assessed by comparing isoflurane-induced vasodilatation between intact and denuded rings. To assess the role of EDHF in the relaxation of intact and denuded rings, the experiment was conducted in phenylephrine preconstricted rings (intact rings $n=12$, denuded rings $n=12$), and in KCl (which inhibits EDHF)[21] preconstricted rings (intact rings $n=12$, denuded rings $n=12$).

The role of nitric oxide was assessed in KCl-preconstricted vessels by comparing isoflurane-induced vasodilatation between intact rings ($n=12$) and rings incubated with an inhibitor of endothelial nitric oxide synthase, Nω-nitro-L-arginine (LNNA) 5×10^{-5} mol $litre^{-1}$ ($n=12$).

The role of prostanoids was assessed in KCl-preconstricted vessels by comparing isoflurane-induced vasodilatation between intact rings ($n=12$) and rings incubated with an inhibitor of cyclo-oxygenase, indomethacin 10^{-5} mol $litre^{-1}$ ($n=12$).

The role of endothelins was assessed in KCl-preconstricted vessels by comparing isoflurane-induced vasodilatation between intact rings ($n=12$) and rings incubated with an inhibitor of smooth muscle cell receptors to endothelins (ET-A receptors), cyclo (-D-trp-D-Asp-Pro-D-Val-Leu) (BQ 123) 10^{-5} mol $litre^{-1}$ ($n=12$).[22 23]

Drugs used in this study were phenylephrine, acetylcholine, LNNA and indomethacin (Sigma Chemical, France), BQ 123 (Neosystem, France) and isoflurane (Abbott, France).

STATISTICAL ANALYSIS

Data are expressed as percentage decrease in tension compared with tensions developed after KCl 40 mmol $litre^{-1}$. Data are expressed as mean (SEM). Data were analysed using ANOVA. Differences were considered significant if $P<0.05$.

Results

Isoflurane produced dose-dependent relaxation in all groups of rings.

In KCl-preconstricted vessels, isoflurane-induced relaxation was significantly greater in denuded than

in intact rings at concentrations of 4% and 5% (table 1). In phenylephrine-constricted vessels, isoflurane-induced relaxation was significantly greater in denuded than in intact rings at concentrations of 4% and 5% (table 2). The difference in vasodilatation between intact and denuded rings was comparable between vessels constricted with phenylephrine and vessels constricted with KCl at 4% isoflurane (23 (4) % *vs* 19 (2) %; ns) and at 5% isoflurane (20 (3) % *vs* 29 (3) %; ns).

Isoflurane-induced relaxation was significantly greater in rings treated with LNNA than in intact rings at concentrations of 4% and 5% and was comparable with relaxation obtained in denuded rings (table 1).

Relaxations were not significantly different between intact rings and rings treated with BQ 123 or indomethacin (table 1).

Discussion

We have shown that isoflurane dose dependently relaxed aortic rings via an endothelium-independent mechanism[1–7] as vasodilatation obtained in intact vessels was present in vessels without endothelium. However, we found that the presence of endothelium modified the response to isoflurane, as denuded vessels were relaxed more than intact vessels.

The fact that vasodilatation was greater in denuded than in intact vessels suggests that isoflurane may have altered endothelial control of vascular tone. To explain such an effect, we hypothesized that isoflurane may either decrease release of endothelium-derived relaxing factors or increase release of endothelium-derived contracting factors[4 7]: of the endothelium-derived relaxing substances, we examined nitric oxide, EDHF and prostacyclin; of the endothelium-derived constricting factors, we examined endothelins and thromboxane A_2.

Nitric oxide is a labile molecule synthesized by endothelium which relaxes vessels by increasing the concentration of 3' 5'-guanosine monophosphate (cGMP) within the vasculature[24] and by hyperpolarizing smooth muscle cells.[25] To assess the role of nitric oxide, we have compared the effect of isoflurane between intact rings and rings incubated with LNNA. We found that vessels treated with LNNA relaxed more than intact rings. This indicates that nitric oxide did not mediate isoflurane-induced vasodilatation but rather modulated this effect. Indeed, if nitric oxide has a role in isoflurane-induced vasodilatation, vessels treated with LNNA should dilate less than intact vessels, and not the contrary. Therefore, we suggest that the fact that relaxation was less in intact compared with LNNA-treated vessels was possibly a result of inhibition of release of nitric oxide by isoflurane. This hypothesis is supported by the study of Brendel and Johns,[7] who showed similar results in the aorta, and by studies which demonstrated that volatile anaesthetics decreased the amount of nitric oxide produced by endothelial cells. The mechanisms involved in this attenuation produced by nitric oxide do not involve smooth muscle cell hyperpolarization as similar results were obtained in the presence of KCl, which inhibits hyperpolarization.[25] Isoflurane-induced decrease in production or stability of nitric oxide[15] may lead to a relative vasoconstriction counterbalancing the relaxation produced by isoflurane.

The effects of endothelium-derived hyperpolarizing factors (EDHF) are not well understood but a vasodilator action has been documented.[26] To assess the role of EDHF in the difference in relaxation between intact and denuded rings, experiments were conducted in vessels constricted with phenylephrine and KCl, which are known to inhibit the action of EDHF.[21] We found that the difference in relaxation between intact and denuded rings persisted in the absence of EDHF. Therefore, we conclude that EDHF did not play a role in modulating isoflurane-induced vasodilatation.

Prostanoids are end products of arachidonic acid metabolism and are synthesized by endothelium via activation of cyclo-oxygenase.[27] Prostacyclin is a vasodilator while thromboxane A_2 is a vasoconstrictor.[27] To assess the role of prostanoids in the difference in relaxation between intact and denuded rings, the effect of isoflurane was compared between intact rings and rings incubated with indomethacin. We found that relaxation in rings treated with indomethacin was comparable with that of intact vessels. Therefore, modulation of isoflurane-induced vasodilatation was not mediated by release of a contracting prostanoid or by inhibition of the release of a relaxing factor.

Endothelins are peptides synthesized by endothelium that act on adjacent smooth muscle cells to produce vasoconstriction.[22] This effect is mediated via activation of specific receptors (ET-A receptors).[22 23] As the difference in relaxation between intact and denuded rings may result from increased production of endothelins, we compared the effect of isoflurane on intact rings and rings incubated with BQ 123, a specific antagonist of ET-A receptors.[23] We found that relaxation of rings treated with BQ 123 was comparable with that in intact rings. Therefore, endothelins do not play a role in modulating isoflurane-induced vasodilatation.

Halothane reduces reperfusion injury after regional ischaemia in the rabbit heart *in vivo*

W. SCHLACK, B. PRECKEL, H. BARTHEL, D. OBAL AND V. THÄMER

Summary

In addition to having anti-ischaemic effects, halothane can protect isolated rat hearts and isolated cardiomyocytes against reperfusion injury of the "oxygen paradox" type. The aim of this study was to investigate if halothane can also protect against myocardial reperfusion injury *in vivo.* Twenty-two rabbits anaesthetized with α-chloralose underwent 30 min of occlusion of a major coronary artery and 2 h of subsequent reperfusion. Seven animals received 1 MAC of halothane for the first 15 min of reperfusion (halothane group), and eight animals served as untreated controls (control group). In seven additional animals, the haemodynamic effects of halothane were antagonized by an i.v. infusion of noradrenaline (halothane–noradrenaline group). We measured cardiac output (CO) by an ultrasonic flow probe around the ascending aorta, left ventricular pressure (LVP) by a tip manometer and infarct size by triphenyltetrazolium staining. Baseline LVP was mean 92 (SEM 4) mm Hg and CO was 289 (16) ml min^{-1}. During coronary occlusion, LVP was reduced to 86 (4) % of baseline and CO to 84 (4)% (similar in all groups). During halothane administration at reperfusion, LVP declined further to 55 (6) % of baseline and CO to 66 (9) % ($P<0.05$ halothane group *vs* control group). Noradrenaline prevented the reduction in LVP (halothane–noradrenaline group 87 (5) % of baseline, control group 84 (6) %) and reduction in CO (halothane–noradrenaline group 89 (5) %, control group 83 (6) %). Infarct size was 49 (6) % of the area at risk in controls and was reduced markedly by administration of halothane to 32 (3) % in the halothane group ($P<0.05$) and to 30 (3) % in the halothane–noradrenaline group ($P<0.05$). Treatment with halothane during the early reperfusion period after myocardial ischaemia protected the myocardium against infarction *in vivo,* independent of the haemodynamic effects of halothane. (*Br. J. Anaesth.* 1997; **79**: 88–96).

Key words
Anaesthetics volatile, halothane. Heart, ischaemia. Heart, reperfusion injury. Heart, myocardial function. Model, rabbit. Rabbit.

The anti-ischaemic effects of halothane were reported as early as 1969 by Spieckermann and colleagues[1] for dog hearts during normothermic ischaemia, and a protective effect of halothane against ischaemic injury was confirmed in several experimental studies.[2–7] Recently, we have shown in isolated rat hearts that cardiac protection by halothane was more pronounced if it was administered after ischaemia during reperfusion than if it was given during the ischaemic period itself,[8] providing some evidence for a protective effect of halothane against the mechanisms of reperfusion injury. Using isolated anoxic reoxygenated cardiomyocytes, it was possible to confirm a protective effect against lethal reperfusion injury of the "oxygen paradox" type and to identify a protective mechanism of halothane against this type of reperfusion injury.[9 10] Halothane 1.5 MAC, given during reoxygenation, prevented reoxygenation-induced Ca^{2+} oscillations at the Ca^{2+}-dependent–Ca^{2+}-release channel of the sarcoplasmic reticulum. These Ca^{2+} oscillations are responsible for cellular hypercontracture and cell death at early reperfusion.[11]

However, a specific protective action of halothane against reperfusion injury is evident only from *in vitro* studies that investigated reperfusion injury of the oxygen paradox type. *In vivo,* the pathophysiology of reperfusion injury is more complex. It is possible that several mechanisms of lethal reperfusion injury may exist, the oxygen paradox being but one; other mechanisms may involve free radicals, activated leucocytes and recurrent ischaemia by vascular obstruction.[12]

In this study, the protective effect of halothane against lethal reperfusion injury was investigated in an *in vivo* animal model with coronary artery occlusion and subsequent reperfusion. Previous *in vivo* studies have found a reduction in myocardial injury under ischaemia–reperfusion conditions in the presence of halothane.[2 13] However, from these studies, it was not possible to distinguish between anti-ischaemic effects and effects against reperfusion injury, because halothane was given before the onset

of ischaemia and during ischaemia. It is known that other negative inotropic drugs (e.g. calcium antagonists[14 15] or beta blockers[16 17]) have potent anti-ischaemic effects when given before or during ischaemia. In this study, we administered halothane only during the initial reperfusion period (15 min). Halothane is known to reduce sympathoadrenergic activity, myocardial inotropy and ventricular loading. To investigate if these haemodynamic effects may be responsible for a myocardial protective effect of halothane *in vivo*, arterial pressure was kept stable in one experimental group by continuous infusion of noradrenaline during administration of halothane.

Materials and methods

The study was performed in accordance with the regulations of the German Animal Protection Law and after obtaining permission from the Animal Care Committee of the District of Düsseldorf.

ANIMAL PREPARATION

After local anaesthesia with EMLA cream, a marginal ear vein was cannulated in 29 New Zealand White rabbits of both sexes, weighing 2.2–4.2 (mean 3.8) kg. The animals were anaesthetized with sodium thiopentone 15–30 mg kg^{-1} i.v. followed by α-chloralose 80 mg kg^{-1} i.v. The trachea was intubated with a Woodbridge tube (3.5 mm id) and ventilation was controlled using a Starling pump (Type 874/052, Braun Melsungen, Germany). Ventilatory frequency was set at 30–35 bpm and tidal volume at 15–20 ml in order to maintain end-expiratory P_{CO_2} at approximately 4.4 kPa (Datex Capnomac Ultima, Division of Instrumentarium Corp., Helsinki, Finland). Arterial blood-gas tensions, haemoglobin concentration and packed cell volume were assessed at regular intervals (before surgery, before the study and at the end of the study). Surface electrocardiogram (ECG, Siemens-Elema AB, Medicins and Technik, Selna, Sweden) was recorded continuously. Anaesthesia was maintained by continuous infusion of α-chloralose 40 mg kg^{-1} h^{-1}. Additional bolus doses were given as needed during surgery. Adequacy of this anaesthesia regimen was demonstrated by lack of muscle movement and haemodynamic responses during surgery.

For measurement of aortic pressure (AOP), a 20-gauge Teflon catheter was advanced from the left carotid artery into the aortic arch and connected to a Statham transducer (PD23, Gould, Cleveland, OH, USA). After cannulation of the external jugular vein, animals received a continuous infusion of normal saline 15 ml kg^{-1} h^{-1} to compensate for fluid losses. Neuromuscular block during thoracotomy was produced with a single dose of pancuronium 0.1 mg kg^{-1} i.v. Body temperature was measured with a rectal thermometer and kept within physiological limits by a heating pad and an infrared lamp.

After median sternotomy and pericardiotomy, an ultrasonic flow probe was placed around the ascending aorta in order to measure left ventricular stroke volume minus coronary flow volume (4S or 6S ultrasonic flow probe, T 208, Transonic Systems Inc., Ithaca, NY, USA). Left ventricular (LV) pressure was monitored using a catheter tip manometer (Micro-Tip Pressure Transducer, Sensodyn S PO SF-1, Braun Melsungen AG, Melsungen, Germany) introduced via the left atrium. A ligature snare was passed around a major coronary artery for later occlusion. After completion of the preparation, the thoracotomy was covered with plastic film to lessen evaporative and convective heat loss. Temperature was measured inside the pericardial cradle (GTH 1160, Digital Thermometer, Geisinger Electronic, Germany) and maintained at 38.5±0.3 °C by adjusting the heating pad and the infrared lamp. Figure 1 illustrates the preparation of the heart.

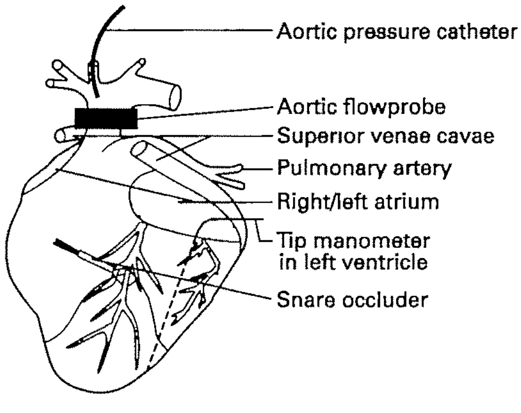

Figure 1 Experimental preparation

EXPERIMENTAL PROGRAMME

Fifteen minutes after surgery had been completed, baseline measurements were performed. In two rabbits, halothane was given in concentrations of 0.5, 0.75, 1.0 and 1.5 MAC in order to assess the haemodynamic effects of halothane on normal myocardium in this experimental preparation during α-chloralose anaesthesia. For the ischaemia–reperfusion experiments, after baseline measurements the prepared coronary artery was occluded by tightening the snare. The effectiveness of this manoeuvre was verified by the appearance of epicardial cyanosis and ECG changes. Ventricular fibrillation during coronary occlusion was treated by electrical defibrillation (5 J, DCS261 Defibrillator, Piekser, Ratingen, Germany). After 30 min of occlusion, the snare occluder was released. Reperfusion was verified by the disappearance of epicardial cyanosis.

After 120 min of reperfusion, the heart was arrested by injection of 20 ml of potassium chloride solution 16 mmol $litre^{-1}$ into the left atrium, quickly excised and mounted on a modified Langendorff apparatus for perfusion with ice-cold normal saline via the aortic root at a perfusion pressure of 40 cm H_2O in order to wash out intravascular blood. After 5 min of perfusion, the coronary artery was re-occluded and the remainder of the myocardium was perfused through the aortic root with 0.2% Evans blue in normal saline for 10 min. Intravascular Evans blue was then washed out by perfusion with normal saline for 5 min. This treatment identifies the area at risk as unstained. The heart was then cut into transverse slices, 2 mm thick. The weight of each slice was measured and the slices were stained in buffered 0.75% triphenyltetrazolium chloride solution at 38 °C to identify viable and necrotic tissue within the area at risk.[18] The area at risk, and the infarcted area, were determined by planimetry. In the rabbit, the volume of the area at risk has to exceed a certain limit before infarction develops.[19] Therefore, animals with an area at risk of less than 0.5 g were excluded from analysis.

Eight rabbits underwent the ischaemia–reperfusion programme without further intervention (control group). In seven rabbits, halothane was added to the inspired gas (Vapor 19.3, Drägerwerke AG, Lübeck, Germany) starting 3 min before reperfusion and continued for the first 15 min of the reperfusion period (halothane group). Halothane was titrated to an end-tidal concentration of 1.4% (Datex Capnomac Ultima, Division of Instrumentarium Corp., Helsinki, Finland) which corresponds to 1.0 MAC in rabbits.[20] In seven rabbits, the haemodynamic effects of halothane were antagonized by simultaneous infusion of noradrenaline 1.12–2.05 μg kg^{-1} min^{-1} (halothane–noradrenaline group).

DATA ANALYSIS

LV pressure, its first derivative d*P*/d*t*, AOP and stroke volume (SV) were recorded continuously on an ink-recorder (Recorder 2800, Gould Inc., Cleveland, OH, USA) and stored on a videotape recorder (SL-C 30 PS, Sony, Tokyo, Japan) using pulse code modulation (VPMD 8–12, Fa. Heim, Bergisch Gladbach, Germany) for later playback and analysis. The data were digitized using an analogue to digital converter (Data Translation, Marlboro, MA, USA) at a sampling rate of 500 Hz and processed later on a personal computer.

Haemodynamic variables

Global systolic function was measured in terms of LV peak systolic pressure (LVPSP) and maximum rate of increase in pressure (d*P*/d*t*max). Global LV end-systole was defined as the point of minimum d*P*/d*t*,[21] LV end-diastole as the beginning of the sharp upslope of the LV d*P*/d*t* tracing.

The time constant of decrease in LV isovolumic pressure (τ) was used as an index of LV diastolic function.[22] τ was calculated according to the formula:

$$P_t = P_0 \times e^{-\frac{t}{\tau}} \quad (1)$$

where P_t=instantaneous pressure; P_0=LV pressure at end-systole and τ=time constant of decrease in isovolumic pressure.

Cardiac output (CO) was calculated from stroke volume and heart rate, rate pressure product (RPP) from heart rate and LVPSP, and systemic vascular resistance (SVR) from mean AOP and CO, assuming a right atrial pressure of 0 mm Hg in the open-chest preparation.

Statistical analysis

Data are presented as mean (SEM). The effects of halothane on normal myocardium were assessed by one-way analysis of variance (ANOVA) for repeated observations. In the ischaemia–reperfusion experiments, statistical analysis was performed by two-way ANOVA for time and treatment (experimental group) effects. If an overall significance between groups was found, comparison was made for each time using one-way ANOVA followed by the Tukey–Kramer post-test when appropriate.

Results

We used 29 animals; one animal died during

induction of anaesthesia, two died from recurrent ventricular fibrillation during coronary occlusion and two animals were excluded because the size of the area at risk was less than 0.5 g. In the remaining 24 animals, complete data sets were obtained (control group, $n=8$; halothane group, $n=7$; halothane–noradrenaline, $n=7$; halothane without coronary occlusion, $n=2$). Four animals had periods of ventricular fibrillation during coronary occlusion; two showed spontaneous defibrillation within 30 s and two needed electrical defibrillation.

HAEMODYNAMIC FUNCTION

Effects of halothane on normal myocardium

In two rabbits, the effect of halothane was tested on normal myocardium (table 1). There was a concentration dependent decrease in LVPSP, d*P*/d*t*max and SVR. CO was maintained at lower concentrations until 1.0 MAC (the concentration used in the ischaemia–reperfusion experiments) and decreased at 1.5 MAC. There was prolongation of τ, reflecting impairment of left ventricular relaxation at higher halothane concentrations.

Ischaemia–reperfusion experiments

Figure 2 shows an analogue reading of the variables in one experiment. Haemodynamic variables are

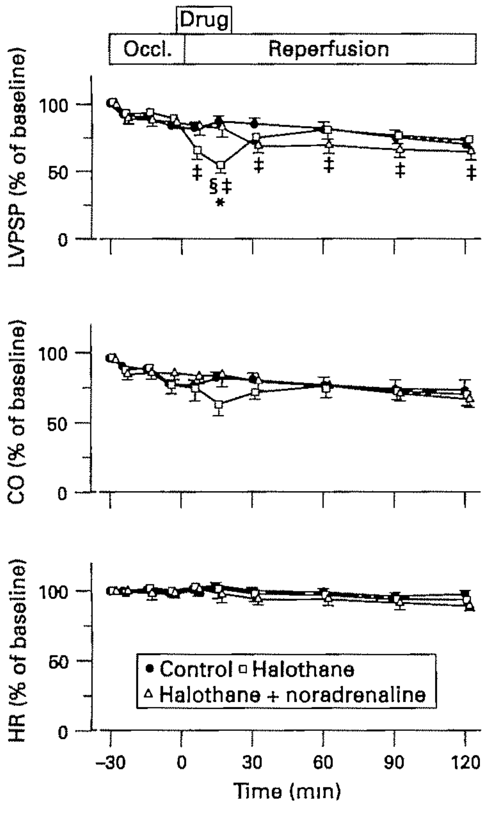

Figure 3 Line plot showing the time course of left ventricular peak systolic pressure (LVPSP), cardiac output (CO) and heart rate (HR) during the study. Data are percentage changes (SEM) from baseline. Mean baseline LVPSP was 96 (SEM 6) mm Hg in the control group ($n=8$), 91 (8) mm Hg in the halothane group ($n=7$) and 89 (7) mm Hg in the halothane–noradrenaline group ($n=7$). Baseline CO was 274 (20) ml min^{-1} in the control group, 309 (30) ml min^{-1} in the halothane group and 285 (36) ml min^{-1} in the halothane–noradrenaline group. Baseline HR was 227 (8) min^{-1} in the control group, 226 (11) min^{-1} in the halothane group and 236 (11) min^{-1} in the halothane– noradrenaline group. Occl.=Time of coronary occlusion; drug=time of halothane or halothane and noradrenaline administration, respectively. $^*P<0.05$ *vs* control; $§P<0.05$ halothane *vs* halothane–noradrenaline. $‡P<0.05$ *vs* baseline conditions.

summarized in figure 3 and table 2. During baseline conditions, the groups were comparable in heart rate (control group 227 (8) beat min^{-1}; halothane group 226 (11) beat min^{-1}; halothane–noradrenaline group 236 (11) beat min^{-1}; $P=0.74$), LVPSP (control group 96 (6) mm Hg; halothane group 91 (8) mm Hg; halothane–noradrenaline group 89 (7) mm Hg; $P=0.76$) and CO (control group 274 (20) ml min^{-1}; halothane group 309 (30) ml min^{-1}; halothane–noradrenaline group 285 (36) ml min^{-1}; $P=0.65$). SVR tended to be higher in the control group during baseline conditions (control group 311 (26) mm Hg litre^{-1} min; halothane group 227 (24) mm Hg litre^{-1} min; halothane–noradrenaline group 234 (55) mm Hg litre^{-1} min; $P=0.18$). RPP as a major determinant of myocardial oxygen consumption was similar in all groups (control group 22.2 (1.9) mm Hg min^{-1} 10^3; halothane group 20.4 (2.0) mm Hg min^{-1} 10^3; halothane–noradrenaline group 21.6 (2.6) mm Hg min^{-1} 10^3; $P=0.31$).

In all groups, coronary occlusion was accompanied by a small reduction in LVPSP (by 13%), d*P*/d*t*max (by 20%) and CO (by 16%) (table 2, fig. 3). Consequently, SVR remained unchanged. The variables of diastolic function showed prolongation of the isovolumic relaxation phase (increase in τ by 26%) and an increase in LVEDP by 2.9 mm Hg during coronary occlusion (table 2) (all values at 25 min of coronary occlusion). In the untreated controls, reperfusion led to a small initial recovery in LVPSP (to 90% of baseline) and CO (to 88% of baseline) at 15 min of reperfusion. Halothane 1.0 MAC, given during the first 15 min of reperfusion, led to a further decline in LVPSP to 55% of baseline values and a decrease in CO (to 66%) and SVR (to 62%). After discontinuation of halothane at 15 min of reperfusion, haemodynamic variables recovered to values not different from controls. In the halothane–noradrenaline group, the decrease in CO and LVPSP during halothane administration was prevented and values were not different from controls. After discontinuation of both drugs, CO remained unchanged, but SVR, LVPSP and d*P*/d*t*max were reduced at 30 min of reperfusion to 70%, 50% and 69% of baseline values, respectively. Heart rate remained unchanged during the experiment in all groups, and consequently RPP was changed primarily in parallel with changes in LVPSP. At the end of the 120-min reperfusion period, LVPSP and CO were reduced to a similar degree in all three groups compared with baseline.

INFARCT SIZE

Mean LV weight was 5.55 (0.21) g; there were no differences between groups (data for individual animals are given in table 3). The ischaemic–reperfused area (area at risk) constituted 30.4 (2.3) % of the LV. In the control group, infarct size was 49.3 (5.7) % of the area at risk (fig. 4). Infarct size was reduced markedly in halothane treated animals (32.2 (2.9) % of the area at risk, $P<0.05$ *vs* control), and to a similar extent in the halothane–noradrenaline treated animals (30.0 (3.4) % of the area at risk, $P<0.05$ *vs* control). The relationship between the size of the area at risk and amount of infarcted tissue is shown in figure 5. The absolute size of the infarcted tissue correlated closely with the size of the area at risk in all groups (control, $r=0.98$; halothane, $r=0.69$; halothane–noradrenaline,

r=0.81). The slope of the regression line relating infarct size and area at risk size was reduced markedly in the halothane (0.21 (0.10), $P<0.001$) and halothane–noradrenaline groups (0.37 (0.12), $P<0.01$) compared with the control group (0.86(0.07)).

Discussion

CRITIQUE OF METHODS

Variables that are considered to be important determinants for development of myocardial infarction are duration of ischaemia, collateral blood flow towards the ischaemic area, size of the area at risk and myocardial temperature during ischaemia. The rabbit has a consistently small collateral circulation[23] and therefore it was not necessary to assess collateral blood flow in the ischaemic area. The rabbit heart, however, may have other ways of supplying oxygen to parts of the area at risk, probably by diffusion or through retrograde thebesian vein circulation.[19] Consequently, there is virtually no infarction in very small areas at risk.[19] Therefore, we excluded from the analysis animals with an area at risk of less than 0.5 g. In addition, we analysed the relationship between infarct size and size of the area at risk to avoid distortion of the results by unaccounted differences in size of the area at risk between groups. Temperature was shown recently to affect infarct size even in the "normothermic range" to a large extent in the open-chest rabbit; a change in infarct size of approximately 10% for each 1 °C was reported.[24] Therefore, in this study, temperature was measured inside the pericardium and kept within a narrow range of 38.5±0.3 °C.

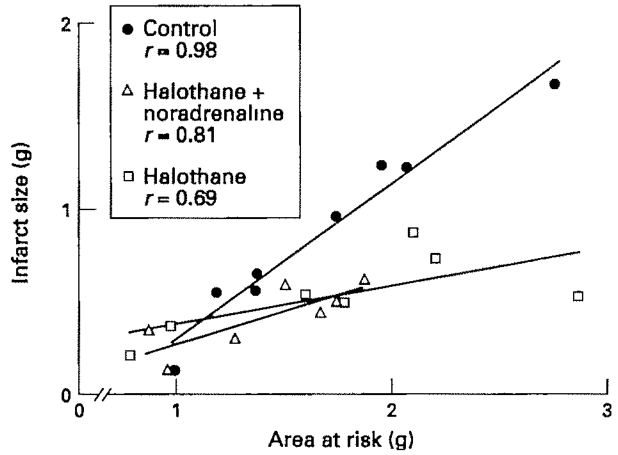

Figure 5 Scatterplot of the relationship between infarct size and size of the area at risk. Slopes of regression lines were smaller in the halothane ($P<0.001$) and halothane–noradrenaline groups ($P<0.01$). Control group, $y=0.86$ (SEM 0.07) $x-0.54$ (0.13); halothane group, $y=0.21$ (0.10) $x+0.18$ (0.19); halothane–noradrenaline group, $y=0.37$ (0.12) $x-0.09$ (0.17).

All experiments were carried out during anaesthesia with α-chloralose. This type of anaesthesia maintains near normal cardiovascular reflexes comparable with the awake state[25] and is a classical anaesthetic for physiological and pharmacological experiments.[26] An anti-ischaemic action of α-chloralose has not been found,[27–29] but we cannot completely exclude interference with reperfusion injury in our study.

As the danger of impending hypercontracture in the reoxygenated myocardial cell is evoked by reactivation of mitochondrial energy production,[30] a protective substance should be present at the onset of reperfusion. In anoxic reoxygenated rat cardiomyocytes, we found that intracellular calcium homeostasis recovered within 5 min[10] and after this period administration of halothane could be discontinued without danger of hypercontracture. For these reasons, we administered halothane 3 min before reperfusion in order to have a stable end-tidal concentration corresponding to 1.0 MAC at the onset of reperfusion, and discontinued halothane after 15 min of reperfusion. Because the rabbit has virtually no collateral circulation[23] allowing halothane to reach the ischaemic myocardium, and because there was only a short period of administration during the last 3 min of ischaemia, a potential anti-ischaemic effect is unlikely to have contributed substantially to the protection.

INTERPRETATION OF RESULTS

Reperfusion of ischaemic myocardium after temporary coronary occlusion initiates structural and biochemical changes that limit the amount of potentially salvageable myocardium (reperfusion injury).[12] In previous *in vitro* studies, we found that halothane markedly reduced the oxygen paradox type of reperfusion injury in isolated hearts[8] and isolated cardiomyocytes.[9] The oxygen paradox was described originally for hypoxic-perfused and reoxygenated isolated hearts and is characterized by abrupt development of hypercontracture and cytolysis after re-supply of oxygen.[31] Cellular hypercontracture depends on several factors: re-supply of ATP by reactivation of oxidative phosphorylation and cycles of transient release and reuptake of Ca^{2+} by the sarcoplasmic reticulum.[32] These calcium cycles trigger uncontrolled activation of the contractile elements,[11] leading finally to cytolysis and cell death, most likely as a result of mutual mechanical disruption of the cells.[33 34] In isolated anoxic reoxygenated cells, halothane prevented these Ca^{2+} oscillations by an action on the Ca^{2+}-dependent–Ca^{2+}-release channel of the sarcoplasmic reticulum.[9 10] This study has extended these findings to the situation of reperfusion after regional myocardial ischaemia *in vivo*, leading to a marked reduction in myocardial infarct size when given during the initial reperfusion period. Other cellular mechanisms affected by halothane are calcium influx via voltage-dependent calcium channels and inhibition of the Na^+–H^+ exchange mechanism.[35] The former is important for the negative inotropic effect of halothane in normal myocardium,[36] but may play only a minor role in the development of lethal reperfusion injury.[37] The latter mechanism has been shown to protect against reperfusion injury[38] by preserving intracellular acidosis and preventing pathological calcium cycling.[11] However, in isolated anoxic reoxygenated cells,[10] recovery of intracellular acidosis was not prolonged in the presence of halothane, suggesting that inhibition of the Na^+–H^+ exchanger by halothane is of minor importance during reperfusion.

In addition to the direct influence on the reperfused myocardium, the haemodynamic effects of halothane during the initial 15 min of reperfusion could have influenced the extent of myocardial damage. During this period, halothane reduced LVPSP and RPP, as a variable of myocardial oxygen demand, by 35% and 34%, respectively. These changes in LVPSP were similar to the effects seen in rabbits without ischaemia–reperfusion. While CO was nearly maintained at 1.0 MAC of halothane in normal hearts, the same concentration was accompanied by a reduction in CO (by 18%) in the presence of regional ischaemia–reperfusion. The effects on myocardial reperfusion injury that result from these changes in ventricular loading conditions and the reduction in myocardial inotropy are not known exactly and experimental data are contradictory. In an *in vivo* dog heart preparation, with 2 h of coronary occlusion the protective effect of 100% ventricular unloading by cardiopulmonary bypass for a 4-h reperfusion period was investigated and resulted in 50% reduction in infarct size.[39] In isolated rabbit hearts, however, complete ventricular unloading had no effect on infarct size.[40] To exclude possible effects of a reduction of ventricular loading conditions by halothane during the initial reperfusion period, we antagonized the negative inotropic and vasodilator effects by continuous infusion of noradrenaline during halothane administration. This treatment effectively prevented the haemodynamic effects during administration of halothane, but there was a small decrease in SVR and, consequently, LVPSP after discontinuation of both drugs. However, these changes were small (LVPSP decreased by 22%) and were too late during reperfusion to explain the marked reduction in infarct size, because lethal reperfusion injury starts with resumption of mitochondrial energy production at the early onset of reperfusion.[30] In addition to its global haemodynamic effects, noradrenaline also acts as a coronary vasoconstrictor. Although coronary flow was not measured in this study, significant coronary vasoconstriction produced by noradrenaline is unlikely because coronary vasoconstriction can be expected to increase infarct size, and in our study the reduction in infarct size by halothane was unchanged by the presence of noradrenaline. In conclusion, it is unlikely that the haemodynamic effects of halothane contributed to the observed myocardial protection.

In vivo, the activated leucocyte is an additional potential cause of (late) lethal reperfusion injury.[41] Although leucocyte activation and accumulation is a consequence of initial state of tissue injury, leucocytes may cause further injury by synthesizing and releasing a variety of mediators, including oxygen-derived free radicals and oxidants.[41] By plugging capillaries, they are thought to play an important role in the "delayed no-reflow phenomenon",[42] resulting in persistent ischaemia. Consequently, leucocyte depletion during reperfusion reduces the "no-reflow" and infarct zones in dog.[43] Halothane anaesthesia may reduce leucocyte activity *in vivo*.[44 45] A reduction in post-ischaemic adhesion of (human) leucocytes in the coronary system of guinea pigs was shown recently in the presence of halothane *in vitro*.[46] Actions on leucocyte activation may have contributed to the myocardial protection observed in this study.

Myocardial reperfusion injury may occur in a variety of clinical settings such as thrombolysis, percutaneous balloon angioplasty and after periods of cardiac arrest during heart surgery with cardiopulmonary bypass. Using isolated rat hearts, it was possible to show that administration of halothane during reperfusion conferred additional cardiac protection after cardioplegic arrest.[47] Further studies must show if the cardioprotective effects of halothane against reperfusion injury are clinically significant.

In summary, we found that treatment with 1.0 MAC of halothane during the early reperfusion period after regional myocardial ischaemia reduced markedly the extent of myocardial infarction *in vivo*. The reduction in infarct size was similar if negative inotropy and vasodilatation were antagonized by infusion of noradrenaline. Therefore, the protection was probably not caused by the haemodynamic effects of halothane, but by a specific action on the reperfused myocardium.

Effects of alfentanil on cerebral haemodynamics in an experimental model of traumatic brain injury†

M. J. SOUTER, P. J. D. ANDREWS, I. R. PIPER AND J. D. MILLER

Summary

Alfentanil is reported to increase intracranial pressure (ICP) after neurotrauma. A direct cerebral vasodilator effect has been postulated. We studied 17 Sprague–Dawley rats allocated to one of three groups. Animals were anaesthetized and their lungs ventilated, and arterial pressure, ICP and/or regional cerebral blood flow (CBF) measurements were undertaken. Group 1 (n=6) received a severe closed head injury while group 2 (n=5) received no injury. ICP and mean arterial pressure (MAP) were measured before, during and after rapid infusion of alfentanil 250, 500 and 750 μg kg^{-1}. CBF was measured by hydrogen clearance before rapid infusions and at 30-min intervals after starting a subsequent slow infusion of alfentanil 500 μg kg^{-1} h^{-1}. Group 3 (n=6) underwent CBF measurement only, for comparison with those of groups 1 and 2. They received an injury but no alfentanil. ICP or MAP values did not differ significantly between groups 1 and 2. Rapid i.v. doses of alfentanil produced increases in ICP and reductions in MAP. ICP changes were consistent with a drug effect (P<0.001) but were small. Reductions in MAP were significant (P<0.05) and preceded changes in ICP. CBF values were similar and unaffected by slow alfentanil infusion in groups 1 and 2, and did not differ significantly between groups 1 and 3. We conclude that alfentanil did not appear to exert a direct effect on the cerebral circulation. Changes in ICP after rapid infusion were secondary to reductions in SAP. Slow infusion did not cause such changes. (*Br. J. Anaesth.* 1997; **79**: 97–102).

Key words
Analgesics opioid, alfentanil. Brain, injury. Brain, blood flow. Brain, intracranial pressure. Rat.

Cerebral perfusion pressure (CPP) is defined as the difference between mean arterial pressure (MAP) entering the skull and intracranial pressure (ICP). ICP can be increased (greater than 20 mm Hg) after trauma by a change in volume of the cranial contents, particularly haemorrhage, swelling secondary to trauma and increased cerebral blood volume (CBV).

In 1989 Marx and colleagues reported that a rapid infusion of alfentanil increased lumbar CSF pressures.[1] He considered that this reflected increased ICP and advised against the use of alfentanil in intracranial hypertension.

In 1992 Moss reported a series of five patients with normal pressure hydrocephalus, all of whom suffered increases in ICP in response to rapid infusions of alfentanil 1 mg.[2] Two of these five patients had only small changes in arterial pressure and the author considered that the effect resulted from a direct cerebral vasodilator action of alfentanil, advising against its use in patients with increased ICP.

We had not observed such a response during administration of alfentanil in our intensive therapy unit (ITU) and, given the widespread use of alfentanil in neuroanaesthesia and ITU, we wished to investigate this phenomenon prospectively in a controlled environment. The aims of this study were to examine the net change in the components of cerebral perfusion (ICP and MAP) in response to rapid i.v. infusions and to assess any change in blood flow or vascular resistance in the brain in response to slow infusions. In this manner, we hoped to examine the two methods by which alfentanil is usually administered. An animal study in a laboratory environment was chosen in order to standardize the cerebral injury and control other physiological variables.

Materials and methods

The study was approved by the Home Office under project licence 60/01228.

We studied 17 male Sprague–Dawley laboratory rats, weighing 320–400 g, allocated to one of three groups. Group 1: rats received a head injury and infusions of alfentanil (n=6); group 2: rats received no injury but did receive alfentanil (n=5); group 3: rats received a head injury alone (n=6).

Rats had free access to food and water until the morning of the experiment. The study sequence consisted of anaesthesia, surgical preparation, insertion of monitoring, and injury or sham.

Accepted for publication: March 11, 1997.

†Presented in abstract form at the Anaesthesia Research Society, Aberdeen Meeting, July 1–2, 1994 (*British Journal of Anaesthesia* 1994; **73**: 713–714P).

Animals received brief exposure to halothane in oxygen and nitrous oxide, which allowed i.p. injection of a mixture of alpha-chloralose and urethane (80 mg+800 mg kg^{-1}, approximately 1 ml/100 g weight). This latter injection provided anaesthesia for the duration of the experiment.

After intubation (16-gauge cannula) and subsequent paralysis with pancuronium 2 mg kg^{-1}, positive pressure ventilation was commenced to normocapnia (Pa_{CO_2} 4.5–5.5 kPa) by the Harvard Rodent ventilator (Harvard Apparatus Ltd, Kent, UK). Hartmann's solution was given i.v. at 2 ml h^{-1} throughout the study.

Arterial pressure was monitored via a cannula in the femoral artery, permitting regular arterial blood-gas analysis. The femoral vein was also cannulated via the same incision. Then, 45–60 min after induction of anaesthesia, the animal received an injury or sham injury, as detailed below. It was then placed in a stereotactic frame, and 2-mm diameter burrholes were drilled under direct microscopy. For ICP monitoring, the lateral ventricle was cannulated via a burrhole under direct microscopy, using a Sprotte 24-gauge spinal needle (Rusch Direct, High Wycombe, Buckinghamshire, UK). This was accomplished using a pressure monitored loss of resistance to mechanical fluid infusion to indicate penetration of the ventricle.

Platinum hydrogen electrodes (150 μm) were inserted into the sensorimotor cortex at a standardized depth of 1 mm. After 30 min, baseline cerebral blood flow (CBF) measurements were obtained, at a time corresponding to 75–90 min after injury. Measurement was made using the hydrogen clearance technique, saturating the rat with inspired hydrogen (10%) and measuring the decrease in current at the cortical electrodes as hydrogen was cleared from cerebral tissues.[3]

The exponential washout curve obtained was transformed logarithmically, and the flow derived from a standardized analysis of the initial rate of decline, representing mixed cortical gray and subcortical white matter blood flow.[4] The first flow measurements were discarded and subsequent flow was recorded.

Physiological variables (i.e. systolic and diastolic arterial pressures, ICP) from data monitoring (Kontron Colormon, Kontron Instruments Ltd, Watford, UK) were downloaded to a computer every 15 s and continuously to chart recorders. Subsequently, rapid i.v. infusions of alfentanil (Janssen Pharmaceutical Ltd, Grove, Wantage, Oxon, UK) 250, 500 and 750 μg kg^{-1} were given. This represents low, moderate and high dosage for the rat.[5-7]

After each dose, MAP and ICP were allowed to return to pre-injection levels or plateau for a period of 5 min before the next dose was given. The rationale of using increasing doses was not to characterize a dose–response curve but to obtain an effect on ICP and MAP. After three rapid i.v. doses, the animal received continuous infusion of alfentanil 500 μg kg^{-1} h^{-1}. CBF was measured after 30 min and repeated at intervals of 30 min.

If CBF was increased, there was an optional arm of the study to give naloxone 40 μg kg^{-1} and then immediately repeat CBF measurements to assess any opioid receptor-mediated effect. This was only required twice and did not prove useful.

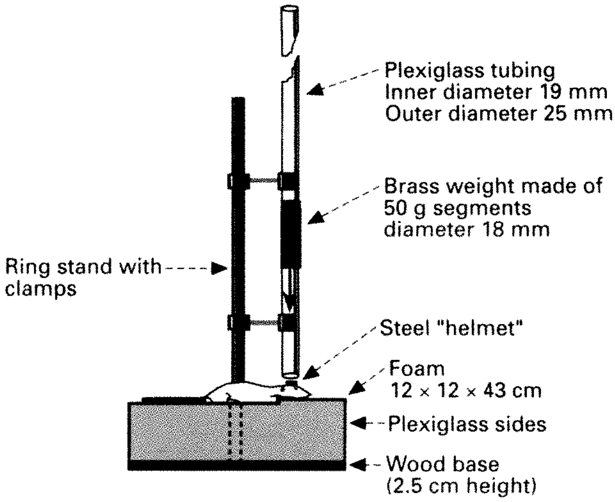

Figure 1 Schematic diagram of the weight drop injury model.

Injury was produced using the impact acceleration model developed by Marmarou and colleagues in Richmond, Virginia and represents a severe brain concussion, both clinically and pathologically.[8] In this model the skull is exposed and a metal disc cemented in the midline between the bregma and lambda. This is considered as a "crash helmet" to protect against skull fracture and ensure diffuse injury. A 450-g weight is then dropped a distance of 2 m onto the helmet (fig. 1).

A characteristic reduction in MAP is observed, the duration of which relates to the severity of the injury.[9] After recovery of MAP from this primary injury, usually within 15 min, ICP was measured as detailed above, and hydrogen electrodes placed.

Data were subjected to analysis of variance (ANOVA) and the Kruskal–Wallis tests for significance testing, and are expressed as mean (SEM) with 95% confidence intervals (CI).

Results

ICP AND MAP

Changes in pressure

Results are categorized for dose of alfentanil and presence or absence of injury, for the first two groups (fig. 2).

Examination of ICP and MAP recordings after rapid infusions revealed that MAP decreased by a mean of 15 mm Hg (SEM 3.3; 95% CI 5.6–23.7), in association with a mean increase in ICP of 5 mm Hg (0.5; 95% CI 3.7–6.6), producing an overall decrease in CPP of 20 mm Hg (3.4; 95% CI 11.2–29.8).

Alfentanil 250 μg kg^{-1}. Group 1 (injury), who received alfentanil 250 μg kg^{-1}, showed a reduction in MAP of 21 mm Hg (8.4; 95%CI −0.6 to 42.6) with an increase in ICP of 7 mm Hg (1.8; 95% CI 2.6–12.1). Group 2 (sham) had a reduction in MAP of 19 mm Hg (13.4; 95% CI −17.9 to 56.5) with an

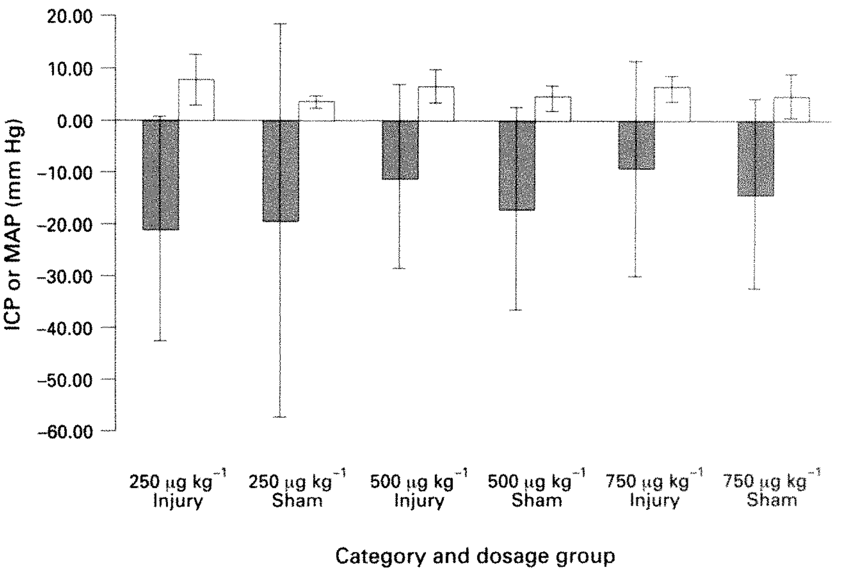

Figure 2 Effect of alfentanil 250, 500 and 750 µg kg^{-1} on ICP (☐) and MAP (▨) in the presence or absence (sham) of injury (mean, 95% confidence intervals).

increase in ICP of 3 mm Hg (0.4; 95% CI 2.1–4.5).

Alfentanil 500 µg kg^{-1}. MAP was reduced by 11 mm Hg (6.7, 95% CI −6.7 to 27.9) and ICP increased by 6 mm Hg (1.2; 95% CI 3.4–9.4) in group 1, while group 2 showed a reduction in MAP of 17 mm Hg (6.9; 95% CI −2.2 to 36) and an increase in ICP of 4 mm Hg (0.9; 95% CI 1.9–6.7).

Alfentanil 750 µg kg^{-1}. In group 1, MAP was reduced by 9 mm Hg (7.9; 95% CI −11.2 to 29.5) and ICP was increased by 6 mm Hg (0.9; 95% CI 3.9–8.5). Group 2 showed reductions in MAP of 14 mm Hg (6.5; 95% CI −4.3 to 32) and increases in ICP of 5 mm Hg (1.5; 95% CI 0.6–8.9).

Changes in ICP were significant ($P<0.001$) throughout the study. Changes in MAP were also significant ($P<0.05$), but were clinically more relevant in that they produced greater net effects on CPP. There were no significant differences between dose or injury groups.

Changes with time

In order to assess which effect had precedence, we examined: (i) time taken from injection until changes were first observed in MAP and ICP; (ii) time until the peak of that change; and (iii) time until recovery from that change.

The initial point of change was defined as the beginning of a pressure transient that at its extreme exceeded two SD of the averages of 10 measurements preceding the initial point of change. The point of recovery was defined as the end of a transient that returned to baseline levels and remained stable thereafter.

(i) Time taken from injection until changes were first observed in MAP and ICP

Averaging all groups, MAP was affected at 13 s (0.6; 95% CI 12–15) and ICP at 22 s (2; 95%CI 16.6–27).

Alfentanil 250 µg kg^{-1}. In group 1, MAP was affected at 13 s (1; 95% CI 10.6–16) and ICP at 14 s (0.5; 95% CI 13.2–15.8). Group 2 experienced an effect on MAP at 15 s (0.2, CI 14–15.2) and on ICP at 27 s (5.6; 95% CI 12.5–41.4) ($P<0.05$).

Alfentanil 500 µg kg^{-1}. Changes in MAP for group 1 were first seen at 11 s (2.4; 95% CI 4.7–17.3) and at 18 s (3.1; 95% CI 10.4–26.2) for ICP. In group 2, changes in MAP started at 15 s (0.2; 95% CI 14.7–15.7) and at 24 s (6; 95% CI 8.6–39.4) for ICP.

Alfentanil 750 µg kg^{-1}. MAP changed in group 1 at 11 s (2.2; 95% CI 5.9–17.1) and ICP at 22 s (3.6; 95% CI 12.7–31.3), while MAP in group 2 changed

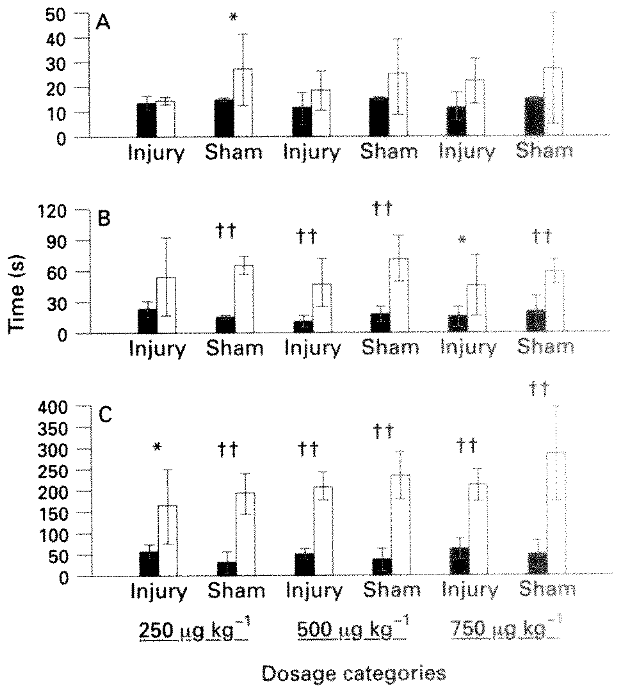

Figure 3 Intervals of changes in MAP (■) and ICP (☐) after rapid infusion of alfentanil 250, 500 and 750 µg kg^{-1} in the presence or absence (sham) of injury (mean, 95% confidence intervals). A: Time to initial changes; B: time to maximum changes; and C: time to recovery. $^{*}P<0.05$; $^{††}P<0.01$.

Table 1 Cerebral blood flow measurements ($\text{ml}\ 100\ \text{g}^{-1}\ \text{min}^{-1}$) in the three groups (mean (95% confidence intervals))

	Time from injury/sham(h)				
	1	2	2.5	3	3.5
Group 1	34.6	36.3	37.6	39.2	
(injury plus alfentanil)	(20.8–48.4)	(19.6–53.1)	(14.3–60.9)	(15.7–62.7)	
Group 2	33.7	37.1	38.3	31.7	34.7
(sham plus alfentanil)	(27.9–39.5)	(25.0–49.2)	(24.2–52.4)	(14.9–48.4)	(2.9–66.6)
Group 3	39.1	59.6	58.5	65.9	
(injury alone)	(30.6–47.7)	(41.8–77.4)	(40.3–76.7)	(44.1–87.7)	

at 15 s (0.2; 95% CI 14.3–15.3) and ICP at 27 s (8.7; 95% CI 4.5–49.5).

There were no significant differences between dose or injury groupings. For all groups, MAP was affected before ICP, irrespective of dose or injury.

(ii) Time until peak of change

The effect on MAP preceded the effect on ICP, with MAP peaking at 17 s overall (1.5; 95% CI 13.5–21.2) and ICP at 57 s (4.2; 95% CI 46.4–67.8).

Alfentanil 250 μg kg^{-1}. MAP changes in group 1 peaked at 22 s (3.6; 95% CI 13.3–31.7) and ICP at 55 s (14.8; 95% CI 16.9–93.1). In group 2, MAP peaked at 15 s (0.3; 95% CI 14.2–15.8) and ICP at 66 s (3.7; 95% CI 56.6–75.4) ($P<0.01$).

Alfentanil 500 μg kg^{-1}. MAP changes for group 1 peaked at 11 s (2.4; 95% CI 4.7–17.3) and ICP at 48 s (9; 95% CI 25.2–71.5) ($P<0.01$). In group 2, MAP peaked at 15 s (0.3; 95% CI 14.2–15.8) and ICP at 72 s (8.7; 95% CI 49.5–94.5) ($P<0.01$).

Alfentanil 750 μg kg^{-1}. MAP changes in group 1 peaked at 15 s (3.9; 95% CI 5.5–25.5) and ICP at 46 s (11.2; 95% CI 16.9–74.4) ($P<0.05$). In group 2, MAP peaked at 21 s (6; 95% CI 5.6–36.4) and ICP at 60 s (4.7; 95% CI 47.8–72.2) ($P<0.01$).

There was no relationship with dose or injury as there were no significant differences between these groupings.

(iii) Time until recovery from changes

This pattern was repeated with time taken from injection until values return to normal. MAP returned to normal by 45 s overall (4.1; 95% CI 34–55) while ICP remained above baseline for 214 s (11.9; 95% CI 183.7–244.8).

Alfentanil 250 μg kg^{-1}. MAP values for group 1 returned to normal at 45 s (12.8; 95% CI 12–78) and ICP at 163 s (33.9; 95% CI 76.3–250.4) ($P<0.05$). In group 2, MAP returned to normal at 52 s (7.5; 95% CI 33.2–71.8) and ICP at 192 s (18.6; 95% CI 144.2–239.9) ($P<0.01$).

Alfentanil 500 μg kg^{-1}. MAP values in group 1 returned to normal at 28 s (9.2; 95% CI 4.4–51.6) and ICP at 209 s (12.5; 95% CI 177.1–241.2) ($P<0.01$). In group 2, MAP returned to normal at 48 s (5.6; 95% CI 33.6–62.4) and ICP by 234 s (22; 95% CI:177.3–290.7) ($P<0.01$).

Alfentanil 750 μg kg^{-1}. Group 1 MAP values returned to normal at 35 s (10.7; 95% CI 7.4–62.6) and ICP at 213 s (14.8; 95% CI 175.2–251.4) ($P<0.01$). In group 2, MAP returned to normal at 60 s (9.5; 95% CI 35.6–84.4) and ICP at 285 s (43; 95% CI 174.6–395.4) ($P<0.01$).

CEREBRAL BLOOD FLOW

Analysis of cerebral blood flow (CBF) at staged times revealed no significant differences between groups 1 and 2 (table 1). Both groups demonstrated little variation in CBF in the 3 h after injury. Comparison between groups 1 and 3 (injury–no alfentanil) showed lower CBF for the alfentanil group (table 1).

At 1 h after injury, group 3 had similar CBF values to alfentanil-treated animals, but by 3 h after injury, CBF increased to a positive difference of 26.7 $\text{ml}\ 100\ \text{g}^{-1}\ \text{min}^{-1}$ but this was not statistically significant.

Discussion

Since the study of Marx and colleagues,[1] when reductions in arterial pressure and increases in lumbar CSF pressure were observed after rapid infusion of alfentanil and sufentanil in patients with supratentorial tumours, there have been various opinions on the effects of alfentanil on cerebral haemodynamics.

Alfentanil had been demonstrated previously to be satisfactory when given by slow i.v. infusion with midazolam, reducing ICP and producing less decreases in MAP and right atrial pressure than fentanyl, suggesting a discrepancy between rapid and slow infusion effects.[10]

Rapid infusions of fentanyl, sufentanil and alfentanil produced negligible effects on brain retractor pressure, which is related to parenchymal pressure.[11] Decreases in MAP and CPP were, however, noted and appeared to be related to the dose of alfentanil. This was demonstrated in both control and injured animals receiving rapid infusions during our study.

A similar effect on MAP was demonstrated by Schregel and colleagues when examining the effect of alfentanil on CBF velocity measured using transcranial Doppler ultrasound.[12] A transient decrease in MAP, coupled with a decrease in mean flow velocity and an increase in pulsatility index, occurred. Subsequently, Moss reported increases in ICP after administration of alfentanil 1 mg by rapid infusion in five patients with normal pressure hydrocephalus who were undergoing pressure compliance tests.[2] The author deduced that because of limited changes in MAP in two of the patients, in contrast with the large reductions in MAP seen in the three other patients, that it was unlikely that the increase in ICP was in response to compensatory cerebral vasodilatation from systemic hypotension. He considered that it was caused by a direct vasodilator effect of alfentanil on the cerebral vessels. However, MAP was monitored only on a minute-by-minute basis using arm cuff arterial pressure measurement which would not detect more transient decreases in MAP. Nevertheless, he advocated discontinuation of rapid infusion of alfentanil in patients at risk of increases in ICP. This view was supported by similar case reports.[13 14]

This supposition of a direct vasodilator effect is in contrast with the results we have obtained, which clearly illustrate an effect on MAP that precedes any changes in ICP. Our data demonstrated that transient decreases in MAP had returned to baseline levels by 1 min, and the frequency of arterial pressure monitoring used by Moss was unlikely to detect such a decrease in MAP and would only demonstrate a persistent increase in ICP of slower onset and longer duration. It has been suggested that the difference in duration between cerebral and systemic vasodilatation is caused by venous outflow resistance, where increases in ICP contribute not only to reductions in perfusion through cerebral inflow vessels, but also to partial or complete occlusion of the large cerebral veins draining the base of the skull causing an increase in cerebral venous volume.[15]

The presumed direct effect was contradicted by another study that year in which children anaesthetized for CSF shunt surgery were given increasing rapid infusions of alfentanil 10, 20 and 40 $\mu g\ kg^{-1}$ i.v. which caused decreases in heart rate, MAP and CPP with all doses.[16] Using shunt as the pressure monitor, ICP did not change from baseline. These children were on the steep slope of the intracranial volume–pressure curve where cerebral volumetric compensatory mechanisms were exhausted and vasodilatation was likely to cause an increase in ICP.

Similarly, rapid infusions of alfentanil 25 and 50 $\mu g\ kg^{-1}$ i.v. were given to neurosurgical and orthopaedic patients, with neurosurgical patients receiving phenylephrine concurrently. Despite this, MAP decreased in both groups with the higher dose, with a clinically insignificant 2-mm Hg increase in ICP in neurosurgical patients.[17] Middle cerebral artery (MCA) velocities decreased in the orthopaedic high-dose group but not in the low-dose group.

No changes in MCA velocity were seen in neurosurgical patients or changes in oxygen extraction, suggesting there was no effect on CBF. This is in keeping with our results, which demonstrated no significant effect on actual CBF when alfentanil was given by slow infusion, and suggests that alfentanil does not exert a primary vasodilator effect on the cerebral vasculature. The transcranial Doppler study by Schregel and colleagues also showed that the cross-sectional area of the MCA was unaffected by alfentanil, suggesting no cerebral vasodilator effect.[12] This was supported further by work measuring the diameter of cerebral arterioles in piglets in response to alfentanil and other opioids. Vasoconstriction rather than vasodilatation occurred. This was attenuated by naloxone and was dose dependent.[18]

This is an interesting observation in relation to the reduction in CBF seen in our study when comparing injured animals receiving a slow infusion of alfentanil with injured animals receiving no alfentanil. Although the differences were not statistically significant, it is tempting to speculate that alfentanil may have attenuated the pathological increase that occurred after head injury alone.

Our study demonstrated that alfentanil reduced CPP when administered by rapid infusion. The likely mechanism of effect on cerebral perfusion, as illustrated by our data, is not via a directly mediated effect on the cerebral circulation, but rather a secondary cerebral vasodilator response to an induced reduction in systemic MAP, resulting in an increase in ICP. This secondary effect persisted beyond the initial reduction and may have appeared as a primary event, depending on the frequency of monitoring.

The important consequence was a reduction in CPP, rather than an effect on ICP, and was of transient duration. Although previous reports have commented on simultaneous reductions in MAP and increases in ICP, there is little information on the duration of effect on CPP. Our data would indicate that it is not prolonged.

There was no evident effect on CBF when alfentanil was given by slow infusion, suggesting that alfentanil does not induce direct vasodilatation.

While recognizing that these results arise from a laboratory model of brain injury, we consider that they are applicable to the human head-injured patient, given that mammalian haemodynamic responses are broadly similar and that dose ranges for the rat were used which are comparable in efficacy with those used in humans.

We consider that alfentanil should not be given by rapid infusion in patients with neurotrauma, especially in view of possible haemodynamic instability. There is no evident contraindication to the use of alfentanil when given by slow i.v. infusion.

Quantitative study of Lowe's square-root-of-time method of closed-system anaesthesia

J. M. Couto da Silva, W. W. Mapleson and M. D. Vickers

Summary

Intermittent injection of liquid anaesthetic into a closed breathing system is particularly suitable in countries with limited resources. A method of calculating appropriate times and magnitudes of the injected doses was described by Lowe but the method has never been assessed rigorously. Such an assessment was the purpose of this study. The technique was used in a double-blind, randomized comparison of halothane, enflurane and isoflurane in oxygen–air, with 20 ASA I or II patients in each group, undergoing superficial or abdominal surgery. The prescribed times of injection were adhered to, but the doses, after the first two, were adjusted to maintain systolic arterial pressure within 20% of the reference preoperative value. Partial pressures of the anaesthetics were monitored but concealed from the investigator–anaesthetist. The mean doses found necessary for each anaesthetic were within 33% of those calculated to produce 1.3 MAC. However, end-tidal partial pressure (just before each dose) stabilized at a steady level of only 0.97, 0.42 and 0.77 MAC for halothane, enflurane and isoflurane, respectively. Recovery from enflurane was much more rapid than that from the other agents but no patient admitted to any dreams. We conclude that the rate of uptake of anaesthetic declines more slowly than predicted and that the patients receiving enflurane were less deeply anaesthetized because the greater hypotensive effect of enflurane led to the use of smaller doses. (*Br. J. Anaesth.* 1997; **79**: 103–112).

Key words
Anaesthetic techniques, low flow. Anaesthetic techniques, closed-system Anaesthetics volatile, halothane. Anaesthetics volatile, enflurane. Anaesthetics volatile, isoflurane.

Lowe,[1] and subsequently Lowe and Ernst,[2] have argued theoretically that if a "priming dose" of liquid anaesthetic is injected into a closed anaesthetic breathing system at 0 min, and a "unit dose" at 1^2, 2^2, 3^2 (1, 4, 9), etc. min, arterial partial pressure of the anaesthetic increases rapidly and then stays constant. Specifically, the priming dose should bring the gas in the breathing system and arterial blood to the specified partial pressure, often taken to be 1.3 MAC; subsequent unit doses should supply uptake to the tissues that occurs during the interval until the next dose. The argument is supported by calculations by Mapleson.[3] It is acknowledged[2] that different patients need different concentrations and therefore different doses, and that these are tailored to the patient by a competent anaesthetist. This technique of anaesthesia is particularly suitable for developing countries.

However, there are two gaps in our knowledge of the method. First, although a closely related method has been studied,[4] the Lowe method has never been subjected to rigorous quantitative assessment. Second, when Couto da Silva and others[5–8] used this method in unblinded studies with halothane, enflurane and isoflurane, they found that the injected volumes of enflurane required to maintain a constant systolic arterial pressure (SAP) were much less than the 1.3-MAC unit dose, and that recovery was more rapid with enflurane than with halothane or isoflurane. However, they could not identify the cause of the discrepancies because they were unable to measure anaesthetic partial pressure.

Therefore, this study was designed to answer four questions on the clinical use of Lowe's method. (1) Are the required doses, and the resulting arterial partial pressures, consistent with Lowe's theory? (2) Can the findings of Couto da Silva be replicated in a double-blind study? (3) If so, can the cause of the discrepancy between agents be elucidated? (4) Whatever the answer to these three questions, does Lowe's method produce satisfactory anaesthesia?

Patients and methods

STUDY DESIGN

On the basis of an exploratory study,[9] 60 adult patients were allocated randomly by a computer program[10] to be anaesthetized with halothane, enflurane or isoflurane (20 patients per group).

J. M. Couto da Silva*, PhD, FACA, M. D Vickers, MB, BS, FRCA, W. W. Mapleson, DSc, FInstP, FRCA (Hon), Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff CF4 4XN. Accepted for publication: January 26, 1997.

*Present address: Department of Anaesthesiology, University of Brasília, Brasília, Brazil.

Correspondence to W. W. M.

Patient and anaesthetist were blinded to the agent used. Inclusion criteria were: ASA status I or II, age 20–65 yr, and upper or lower abdominal, or superficial surgery lasting at least 75 min. Exclusion criteria were: halothane anaesthesia within the previous 3 months; heavy intake of alcohol; cardiac, pulmonary, neurological or renal disease; patients receiving any drug that could alter the MAC of the anaesthetics; and pregnancy. Informed, verbal consent was obtained from all patients and the study was approved by the relevant local research Ethics Committee.

Patients were anaesthetized according to the square-root-of-time method, with a specified partial pressure of 1.3 MAC, and as practised in developing countries except as follows. To assist in blinding, the dose at 0 min was 2 ml for all three anaesthetics and that at 1 min was 1, 1.5 or 2 ml according to body weight (less than 60 kg, 60–75 kg and greater than 75 kg, respectively). These doses were justified by the exploratory study.[9] The prescribed times of subsequent doses were adhered to, but the doses were chosen by the anaesthetist as those most likely to maintain or regain the required depth of anaesthesia. "Normal" depth was defined primarily as an SAP within 20% of a reference preoperative SAP, with some allowance for other clinical signs (heart rate, sweating, tears). The times from opening the breathing system to four stages of recovery were recorded and, on the day after operation, four questions were used to determine the patient's memory and opinion of the anaesthetic (see below).

Monitoring additional to that required for the above was carried out, but all results for the critical variable, partial pressure of the anaesthetic, were concealed from the anaesthetist until the end of the study. End-tidal partial pressure was used as the best, ethically acceptable estimate of arterial partial pressure. In particular, the value just before each injection was used because, first, that is the moment within each dose interval when, according to the theory,[2] arterial partial pressure should be at the specified level, and second, it was also the moment when there was a minimum in the rate of uptake and hence in the arterial to end-tidal partial pressure difference.

All anaesthetics were given by one anaesthetist (J. M. C. da S.) in a standard manner, with no supplementary drugs likely to affect MAC or arterial pressure; all ward visits were to be made by that anaesthetist.

If there were any deviations from the study design or any fault in the apparatus or recordings, the results for that patient were excluded from analysis and the name of the corresponding volatile anaesthetic returned to the randomization pool.

MEASUREMENTS AND OBSERVATIONS

For control of depth of anaesthesia

Control of depth of anaesthesia depended primarily on SAP in relation to a "reference" preoperative value. Therefore, first, SAP was measured three times, at intervals, during the preoperative visit and twice in the anaesthesia room. The mean of the two lowest of these five measurements was taken as the "reference" SAP. Second, the same non-invasive arterial pressure monitor (UA731 Auto-inflation-Takeda Medical Inc.) was used on the ward and in the anaesthesia room in all patients; a different monitor (Hewlett Packard No. 78352) was used in theatre on all patients, but the two instruments were used on opposite arms of several patients in the anaesthesia room to check that they gave consistent readings. In theatre, arterial pressure was measured immediately before each injection of liquid anaesthetic and 3 min after those from 4 min onwards.

Both instruments also indicated heart rate which was noted each time arterial pressure was measured. Reference heart rate was taken as the mean of the three ward measurements. Sweating and tears were noted as present or absent just before each injection. Any tears were then dried.

For answering the questions posed

A Normac Anaesthetic Agent Monitor (AA-102 Datex Instrumentarium, Helsinki, Finland) was used for measuring anaesthetic partial pressure throughout anaesthesia. It drew a sample flow of approximately 200 ml min^{-1} from a side arm on the patient Y-connector and returned it to the expiratory limb of the closed breathing system. The Normac was calibrated before and after each case, using the calibration canisters supplied by the manufacturer; zero was checked occasionally during each case by briefly sampling room air. End-tidal partial pressure just before each injection of anaesthetic was measured from the chart output, correcting for any slight sensitivity change or zero drift. This gave readings as percentage of ambient atmospheric pressure; therefore barometric pressure was measured to correct to percentage of a standard atmosphere. (This was not done automatically by our Normac.)

Extensive laboratory experiments tested the stability over time of the sensitivity of the measurement system, and the consistency between calibrating mixtures. These showed[10] that drift with time was generally within 2% over 5 h, that the pooled SD between different canisters (on any given day) was 1% of the indicated value and that the sensitivities to the contents of the canisters were within 4% of those of gravimetric mixtures of halothane, enflurane or isoflurane in air, made up in the laboratory.

The four stages of recovery of the patient were those used by Saraiva and colleagues[11]: responds to painful stimulus, obeys commands, answers a simple question, and is fully orientated in time and space.

The four questions used on the day after operation were: (a) What is the last thing you remember before going to sleep? (b) What is the first thing you remember after waking up? (c) Did you have any dreams? (If "yes", what were they?) (d) Would you accept the same type of anaesthetic again?

For supplementary information

A Platon GSYV flowmeter (Platon Flowbits Ltd, Hampshire, UK) (50–500 ml min^{-1}) was placed downstream of the Rotameter of the anaesthesia machine to obtain more accurate and precise measurement of oxygen inflow. A Kontron fuel cell measured continuously oxygen concentration in the inspiratory limb of the breathing system. Body temperature was monitored by an oesophageal probe connected to the Hewlett Packard monitor. The readings of these three monitors were noted just before each injection.

Carboxyhaemoglobin concentration was measured (Ciba-Corning Co-oximeter M2500) in blood samples obtained just before induction and just before opening the breathing system for recovery.

For routine clinical monitoring

Arterial saturation was monitored continuously with a pulse oximeter (Novametrix 515); the Hewlett Packard monitor displayed ECG and heart rate. Also, between the later, widely spaced injections, it automatically measured SAP every 5 min. End-tidal carbon dioxide concentration was monitored by a Datex Normocap instrument, sampling at approximately 100 ml min^{-1} from the catheter mount for only a few breaths just before each injection, without returning the sample to the breathing system.

PROCEDURE

The circle breathing system

The system had an internal volume of 8 litre. It comprised a jumbo soda-lime canister, 2-litre rubber reservoir bag at the end of 1-m length of rubber corrugated tubing, Y-piece and two 1-m corrugated rubber tubes in each limb. The tube at the anaesthetic-machine end of the expiratory limb had a thickened wall at each end. A 25-gauge needle, mounted on an empty 2-ml glass syringe, penetrated the thickened wall at the machine end. For each injection, the empty syringe was replaced by an appropriately loaded syringe and its contents injected.

No more than two patients were studied on any one day. To reduce cross contamination of anaesthetics, two sets of tubing and reservoir bag were maintained and flushed with oxygen overnight after use. The soda-lime canister was flushed with oxygen 6 litre min^{-1} overnight before use and the soda-lime was changed before the second patient in one day. Laboratory experiments[10] showed that with these precautions, cross contamination was always less than 0.05% of an atmosphere.

Apart from the two sets of tubing and bag, the same apparatus was used for all 60 patients with meticulous attention to the sealing of potential leaks and a routine pressure test before each anaesthetic. In the 30 min before induction of anaesthesia, a sequence of operations[10] left the breathing system filled with 55–65% oxygen in nitrogen and ready for an almost loss-free connection to the patient.

Anaesthesia

Patients were premedicated with temazepam 10–30 mg (according to body mass), 1 h before operation. Anaesthesia was induced in the operating theatre with etomidate 0.4 mg kg^{-1} i.v. One-third of the dose was given first, followed by suxamethonium 1 mg kg^{-1} i.v. The patient's lungs were ventilated manually by mask for 1 min, using a Bain breathing system with a fresh-gas flow of oxygen 6 litre min^{-1}; the remainder of the etomidate was then given. After a further 15 s the patient's trachea was intubated with a cuffed tube, the cuff was inflated, breath sounds were checked and the patient was connected to the circle breathing system. Oxygen inflow was set to the estimated metabolic consumption, and the preset 0-min and 1-min doses were injected as described above.

Thereafter, for a "normal" desired depth of anaesthesia, if SAP just before any dose was due was within 20% of the reference SAP, the general rule was that the previous dose of liquid anaesthetic should be repeated; if SAP was more than 20% greater than the reference, a suitably larger dose was given; if more than 20% below, a smaller dose. This rule was ignored if other signs (increasing heart rate, sweating, tears or, very seldom, extrasystoles) suggested that a larger dose was needed. If a dose was due shortly before the anticipated end of surgery, the required depth was recorded as "light" and the dose was omitted or a small dose given. All doses were recorded.

Manual ventilation was used throughout anaesthesia, with neuromuscular block maintained with vecuronium: a dose of 0.1 mg kg^{-1} i.v. was given as soon as the effects of suxamethonium began to wear off, followed by additional smaller doses as required. In accordance with local routine practice, crystalloid and sometimes colloid solutions were administered generously, but blood was given only when the estimated blood loss exceeded 20% of the estimated blood volume. Oxygen inflow was adjusted to maintain the volume of the reservoir bag.

At the end of surgery, neuromuscular block was antagonized with neostigmine 2.5 mg and atropine 1.2 mg i.v. and oxygen inflow was increased to 6 litre min^{-1}. When breathing was adequate, the patient was taken to the recovery room breathing oxygen-enriched air from a Hudson mask. Recovery was followed by the anaesthetist, noting the times from opening of the breathing system to each of the four defined stages. The patient was then returned to the ward.

Blinding

For each patient, the anaesthetist was provided with one of a set of identical dark bottles, containing the appropriate liquid anaesthetic, and a sealed opaque envelope containing the name of the anaesthetic. Both were marked only with the serial number of the patient. After the Normac analyser had been calibrated, an assistant opened the envelope, depressed the appropriate selector button on the analyser and concealed the face of the analyser and the chart record from the anaesthetist throughout the case. To avoid identification of the anaesthetic by smell, the anaesthetist put a few drops of peppermint oil on his surgical mask before opening the numbered bottle of anaesthetic. At the end of the anaesthetic, the assistant rolled up the chart record, sealed it for later analysis and selected enflurane on the analyser so that the anaesthetist could perform the final calibration, still blind. The anaesthetist also wrote down his surmise as to which anaesthetic he had been using. Finally, the assistant marked the anaesthetic on the anaesthetic record card.

DATA PROCESSING AND STATISTICAL ANALYSIS

As a reference level for measured end-tidal partial pressures of the anaesthetics, MAC (as a percentage of a standard atmosphere) was calculated from:

$$\mathrm{MAC}=a\times 10^{bx} \qquad (1)$$

where x=difference in age in years from 40, $b=-0.00269$ and a=MAC at age 40 (0.75%, 1.63% and 1.17% for halothane, enflurane and isoflurane respectively).[12]

As a reference for the actual doses used, the theoretical unit dose, D, for 1.3 MAC was calculated from[2]:

$$D=1.3\times(\mathrm{MAC}/100)\times 2\lambda Q/r \qquad (2)$$

where λ=blood–gas partition coefficient (2.4, 1.9, 1.4 respectively[13]); Q=cardiac output in litre min^{-1}, estimated from $0.2\times M^{3/4}$,[2] where M=body mass in kg and r=ratio of vapour volume at 37 °C to liquid volume (240, 210, 206 respectively[2]). This leads to unit doses of 0.94, 1.86 and 1.00 ml for a 70-kg patient aged 40 yr. Strictly, the dose at 0 min, the "priming" dose, should be calculated differently,[2] but the result is usually very similar so the distinction was ignored as is customary among practitioners of the method.

Comparisons between the three agents were generally by one-way analysis of variance (ANOVA), preceded by a log transform for some variables to make the distribution more nearly normal. Where the ANOVA showed a significant difference between anaesthetic agents, comments on individual agents are generally made only when the 95% confidence intervals of an estimate exclude some expected value. For the irredeemably non-normally distributed volumes of infusion fluid, the Kruskal–Wallis test was used. The chi-square test was used for counts.

Where required, trends of measurements with time were assessed as recommended by Matthews and colleagues[14]: first a straight line or a parabola was fitted to the results for each patient, then simple statistics were performed on the resulting sets of coefficients (intercept, slope, and curvature), weighting each coefficient in inverse proportion to its variance, as provided by the GLIM package[15 16] used for the trend analysis and ANOVA.

Results

Ninety patients were studied because the results from 30 were discarded for a total of 33 reasons: deviations from study design (eight), faults in the recordings (14), leaks from the breathing system (five) and duration of anaesthesia less than 75 min (six).

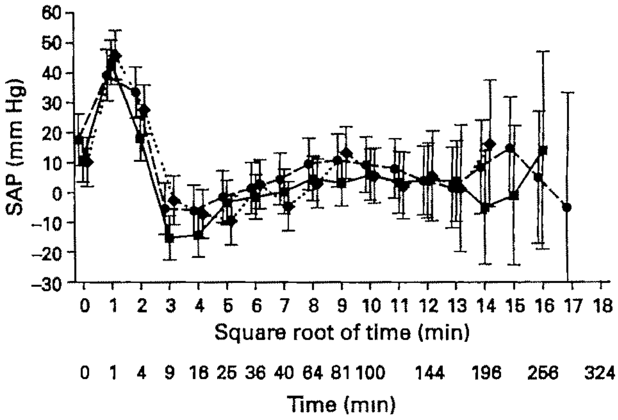

Figure 1 Mean and 95% confidence intervals of systolic arterial pressure (SAP) before each injection (as a difference from the reference SAP), against the square root of time, for the three anaesthetics. The positive drift from 9 min onwards is adequately described by a common slope of 1.9 (SEM 0.28) mm Hg per dose interval ($P<0.001$). At the later times the means become erratic and the confidence limits wider because the number of patients still anaesthetized becomes progressively fewer. Data for enflurane (●) and isoflurane (◆) have been slightly time-shifted relative to halothane (■) to clarify the display.

Table 1 Patient data. s=Superficial, u=upper abdominal, l=lower abdominal

	Sex (M/F)	ASA grade (I/II)	Age (yr)	Weight (kg)	Height (m)	Surgery (s/u/l)	Duration of anaesthesia (min)
Halothane							
n	6/14	13/7				10/4/6	
Mean			43.6	69.9	1.65		137.4
Range			21–65	43–95	1.51–1.85		79–258
Enflurane							
n	6/14	11/9				6/7/7	
Mean			45.4	68.0	1.63		169.1
Range			25–63	50–104	1.43–1.85		79–306
Isoflurane							
n	10/10	13/7				5/9/6	
Mean			45.4	63.5	1.66		130.3
Range			20–65	48–82	1.50–1.80		76–210

The three groups of patients were similar in most respects but mean duration of anaesthesia was greater in the enflurane group (table 1).

PREOPERATIVE RESULTS

The doses of etomidate and suxamethonium were fixed on a mg kg^{-1} basis. For the other preoperative variables, the ranges of mean values for the three groups of patients were: temazepam dose 0.323–0.325 mg kg^{-1}, reference SAP 127–128 mm Hg and reference heart rate 79–82 beat min^{-1}.

PEROPERATIVE RESULTS

Haemodynamic variables

SAP increased sharply initially but from 9 min onwards it was, on average, close to the reference SAP for all three anaesthetic agents with a slow but significant ($P<0.001$) positive drift of 1.7 mm Hg per dose interval, from a little less than the reference SAP to a little more (fig. 1). From 9 min onwards, 86% of individual measurements were within 20% of the reference SAP. This was true both immediately before, and 3 min after, each injection, with a mean decrease of 3–4 mm Hg in that 3 min. Differences between agents were small (<1 mm Hg) and non-significant.

Mean heart rate (before injection) from 9 min onwards was significantly greater than the reference heart rate for enflurane and isoflurane (by 11 and 17 beat min^{-1}, respectively). With each injection there was a mean decrease of 4 beat min^{-1} with halothane.

Clinical signs

Sweating was never observed during the study; tears were recorded only at 1 or 4 min, for six, nine and four patients in the halothane, enflurane and isoflurane groups, respectively. The differences were not significant.

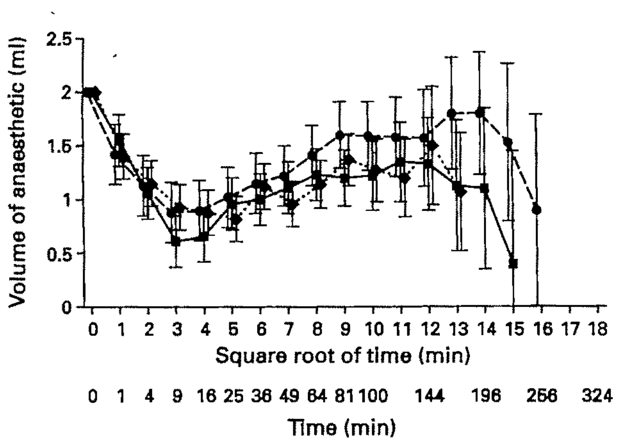

Figure 2 Mean and 95% confidence intervals of the volumes of injected liquid anaesthetic, against the square root of time, for the three anaesthetics. The final volume was omitted from the calculations when the required depth of anaesthesia at that time was recorded as "light". The positive drift from 9 min onwards is adequately described by a common slope of 0.066 (SEM 0.013) ml per dose interval ($P<0.001$). Data for enflurane (●) and isoflurane (◆) have been slightly time-shifted relative to halothane (■) to clarify the display.

Table 2 Mean volume of liquid anaesthetic injected at each dose (excluding the last if the required depth at that time was "light"): actual, predicted (equation 1) and ratio, and also revised predicted (see discussion) and ratio. Calculated as follows: for each patient, mean of all measurements; for each anaesthetic, mean and SD of these patient means and 95% confidence interval (CI) of the resulting mean. Therefore, SD refers to variation between patients. P=Probability (by one-way analysis of variance) that the differences between anaesthetics are caused by chance. [a]Predicted from equation (2) for 1.3 MAC. [b]Predicted for mean actual pre-injection end-tidal partial pressure (table 3)

	Mean	SD	95%CI	P
Actual volume (ml)				
Halothane	1.144	0.354	0.98–1.31	
Enflurane	1.316	0.399	1.13–1.50	ns
Isoflurane	1.176	0.280	1.04–1.31	
Predicted volume[a] (ml)				
Halothane	0.921	0.174	0.84–1.00	
Enflurane	1.761	0.369	1.59–1.93	—
Isoflurane	0.901	0.124	0.85–0.96	
Ratio (actual/predicted)				
Halothane	1.237	0.293	1.10–1.37	
Enflurane	0.752	0.184	0.67–0.84	<0.001
Isoflurane	1.327	0.366	1.16–1.50	
Revised predicted[b] volume (ml)				
Halothane	0.743	0.354	0.58–0.91	
Enflurane	0.586	0.158	0.51–0.66	0.03
Isoflurane	0.550	0.157	0.48–0.62	
Ratio (actual/revised-predicted)				
Halothane	1.709	0.547	1.45–1.96	
Enflurane	2.315	0.638	2.02–2.61	0.001
Isoflurane	2.190	0.353	2.03–2.36	

Cardiovascular complications (SAP less than 60% of the reference value, heart rate less than 50 beat min^{-1} or greater than 120 beat min^{-1}, AV junctional rhythm or arrhythmia, or a combination of these) occurred at some time during anaesthesia in 14 patients with halothane, four with enflurane and eight with isoflurane—an overall incidence of 43%. The differences were significant ($P<0.01$).

Anaesthetic variables

Mean volumes of liquid anaesthetic injected showed some systematic variation with time (fig. 2) but were similar for all three agents despite the differences in predicted unit dose. Therefore, for each patient, the following values were calculated: predicted dose, mean actual dose (omitting the last one if the required depth at that time was recorded as "light") and the ratio of the two. These were then averaged for each agent. This showed (upper part of table 2) that the mean enflurane dose was 25% less than that predicted and the mean halothane and isoflurane doses were 24% and 33% more, respectively ($P<0.001$).

The type of surgery had no significant effect on the amount of anaesthetic required, either in terms of absolute dose ($P=0.7$) or relative to the predicted dose ($P=0.5$).

In all patients the anaesthetic partial pressure showed a sawtooth pattern in end-inspired and end-tidal values and in the amplitude of the difference between them (fig. 3): all three aspects increased rapidly after each dose, reached a peak in approximately 3 min and then decreased slowly until the next dose.

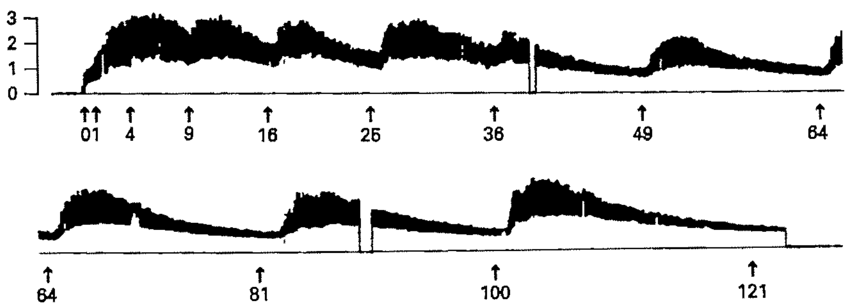

Figure 3 Sample recording of anaesthetic concentration against time. The background grid has been suppressed; a calibration scale (% atmosphere enflurane in this example) and a zero line have been added. Arrows indicate the time in minutes at which each injection was due. Note the sawtooth pattern in inspired (upper limit of trace) and end-tidal (lower limit) concentrations produced by periodic injections of liquid anaesthetic at the times indicated. Note also the occasional zero checks and that no injection was made at 121 min.

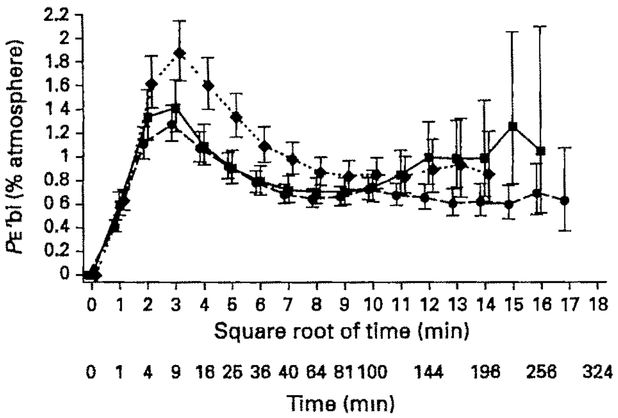

Figure 4 Mean and 95% confidence intervals of pre-injection end-tidal partial pressure (*P*E'bi) against the square root of time, for the three anaesthetics. The apparent positive drift for halothane after 49 min was not significant (P=0.5) and arose partly because some of those patients who underwent prolonged halothane anaesthesia had consistently large values of *P*E'bi throughout anaesthesia. Data for enflurane (●) and isoflurane (◆) have been slightly time-shifted relative to halothane (■) to clarify the display.

End-tidal partial pressure just before each injection (*P*E'bi) was not constant: the means for each agent (fig. 4) increased to a peak at 4–9 min and stabilized at a steady level from 49 min onwards. The apparent positive drift with halothane at the later times was not significant (P=0.5) and was partly because some of those patients who underwent prolonged anaesthesia with halothane had consistently large values of *P*E'bi throughout anaesthesia.

Table 3 Geometric mean pre-injection end-tidal partial pressures of anaesthetics (averaged from 49 min onwards). Calculated as follows: (a) logs of all measurements; (b) for each patient, mean of all logs; (c) for each anaesthetic, mean and SD of these log means, that is variation between patients, and 95% confidence interval (CI) of the resulting mean for each anaesthetic; and (d) convert means and CI (but not SD) back to linear values. P=Probability (by one-way analysis of variance) that the differences between anaesthetics are caused by chance. *Corrected for age according to equation (1)

	Geometric mean	SD of logs	95%CI	P
Pre-injection end-tidal partial pressure (% std atmosphere)				
Halothane	0.709	0.182	0.58–0.86	0.048
Enflurane	0.670	0.118	0.59–0.76	
Isoflurane	0.870	0.141	0.75–1.01	
Pre-injection end-tidal partial pressure (MAC* units)				
Halothane	0.967	0.168	0.81–1.16	<0.001
Enflurane	0.425	0.109	0.38–0.48	
Isoflurane	0.769	0.137	0.66–0.89	

Steady-state partial pressures were summarized by averaging, for each patient, all *P*E'bi values from 49 min onwards, calculating means of these averages for each anaesthetic and also expressing them in MAC units, corrected for age (table 3). The differences between anaesthetics in terms of actual partial pressure were small but, in terms of MAC units, the differences were large (approximately 1, 0.5 and 0.75 MAC for halothane, enflurane and isoflurane, respectively) and highly significant (P<0.001).

Other variables

Mean rates of vecuronium use were 1.4–1.5 μg kg^{-1} min^{-1} for the three groups. Hartmann's solution was used in all patients, colloids in approximately 50% and packed red cells in less than 25%. Mean total fluid use ranged from 13 ml kg^{-1} h^{-1} for isoflurane to 16 ml kg^{-1} h^{-1} for halothane. There were no significant differences between anaesthetics in any of these features.

From 9 min onwards overall mean oxygen inflow required to maintain the volume of the breathing system was 212 ml min^{-1} (STPD) with negligible drift and no significant differences between anaesthetics. Allowing for an estimated oxygen leakage of 36 ml min^{-1} (see discussion below) this gives an oxygen consumption of 176 ml min^{-1}, close to the 179 ml min^{-1} predicted by Nunn[17] for our average patient (table 1).

Inspired oxygen concentration was similar for the three agents and averaged 58% overall with all instantaneous values between 42% and 88%.

Overall mean end-tidal $P\text{CO}_2$ was 5.0 kPa and overall mean arterial saturation by pulse oximetry was 99%; there were very small differences (<1%) between groups. The lowest recorded saturation was 95%. All but three individual values of end-tidal $P\text{CO}_2$ were between 4.0 and 5.9 kPa.

Oesophageal temperature decreased from an overall mean of 36.3 °C to 35.8 °C at 64 min.

Overall mean carboxyhaemoglobin concentration changed from 2.8% before operation to 3.0% at the end of anaesthesia, with 95% confidence limits for the mean change of −0.1 to +0.4%.

Table 4 Recovery times (min). Analysis performed on log time. *P*=Probability (by one-way analysis of variance) that the differences between anaesthetics are caused by chance

	Geometric mean	SD of logs	95%CI	*P*
Stage 1: patient responds to painful stimulus				
Halothane	2.1	0.304	1.5–2.9	
Enflurane	1.5	0.182	1.2–1.8	0.01
Isoflurane	3.0	0.411	1.9–4.7	
Stage 2: patient obeys command				
Halothane	7.1	0.281	5.2–9.6	
Enflurane	4.1	0.190	3.3–5.0	0.001
Isoflurane	8.8	0.331	6.2–12.5	
Stage 3: patient answers a simple question				
Halothane	12.3	0.272	9.2–16.5	
Enflurane	7.4	0.212	5.9–9.3	0.001
Isoflurane	15.0	0.278	11.1–20.3	
Stage 4: patient is fully orientated in time and space				
Halothane	17.5	0.243	13.5–22.7	
Enflurane	10.8	0 224	8.5–13.7	0.002
Isoflurane	20.3	0.263	15.3–26.9	

Table 5 Responses to the question "What is the last thing you remember before going to sleep?" *P*=Probability (by chi-square test) that the difference between anaesthetics is caused by chance. *"I am going to put you to sleep"

	Premedication	Being in theatre	Information*	Pain of etomidate injection	*P*
Halothane	5	2	9	4	
Enflurane	0	4	13	3	0.14
Isoflurane	3	7	8	2	

Table 6 Success rate in identifying the anaesthetic used. The chance success rate for each cell is 6.7, with 95% confidence limits of 2.5 and 10.8. Overall probability that success rate is caused by chance (by chi-square test): *P*<0.001

Anaesthetist's opinion	Agent actually used			Total
	Halothane	Enflurane	Isoflurane	
Halothane	16	2	5	23
Enflurane	2	6	9	17
Isoflurane	2	12	6	20
Total	20	20	20	60

POSTOPERATIVE RESULTS

In the enflurane group all four stages of recovery were reached in approximately half the time taken in the isoflurane group; the times for the halothane group were intermediate (table 4). Differences between groups were significant.

On the day after operation, memory of the later preoperative events was more frequent in patients in the enflurane group than in the two other groups (table 5) but the differences were not significant (*P*=0.14). In all three groups, six patients remembered the recovery room; 14 remembered nothing before their return to the ward. No patient reported dreams and all said that they would accept the same type of anaesthetic again.

The anaesthetist was generally able to identify the use of halothane, but scored only in accordance with chance in correctly identifying enflurane and isoflurane (table 6).

Discussion

THE FOUR QUESTIONS

Are the doses and end-tidal partial pressures consistent with Lowe's theory?

The theory is that, if the predicted dose is given at the specified times, arterial partial pressure increases rapidly to the specified level and then remains constant, but there needs to be "procedural modifications according to patient response".[2] In this study the specified level was 1.3 MAC, the doses were given at the specified times, but the sizes of the doses, after the first two, were chosen primarily on the basis of maintaining normal SAP.

Anomalies of dosage. Although all mean actual doses for each anaesthetic were within 33% of predicted (upper part of table 2), steady state values (49 min onwards) of *P*E'bi were much less than 1.3 MAC (table 3). Accordingly, the predicted doses for these actual *P*E'bi were much smaller and the actual doses were about twice these revised predicted doses (lower part of table 2).

This excess of actual dosage over predicted dosage corresponded to an average excess rate of usage of anaesthetic of approximately 11 ml of vapour per minute. An alternative estimate of excess usage of anaesthetic was obtained from the positive drift of dosage with time (fig. 2) which corresponded to a steady loss of 7 ml of vapour per min.

Several factors could contribute to the apparent need for this excess of 7–11 ml of vapour per min: diffusion into and through the walls of the breathing system; loss in gas leaking from the system; direct uptake into fat from adjacent tissues[18]; metabolism, particularly of halothane[19]; and the fact that, during the period of interest (9–121 min), the theoretical[3] rate of uptake declines a little more slowly than in accordance with the square root of time. Quantitative estimates of these factors (based on laboratory experiments for absorption into the walls of the breathing system) were sufficient to account for a total of 9 ml of vapour per min. Although loss through the skin would be negligible,[20] there may have been appreciable loss through the operation wound, especially in those patients undergoing abdominal surgery.[21] Similar excesses of uptake over that predicted from the square-root-of-time theory have been reported by others for continuous-inflow versions of the Lowe method.[22]

Anomalies of end-tidal partial pressure. The clinical aim was to maintain SAP close to the reference level. Therefore, it is not surprising that *P*E'bi showed an initial "overpressure" before reaching a steady level (fig. 4). However, as SAP returned to the reference level within 9 min (fig. 1), it is at first surprising that the *P*E'bi overpressure lasted until 49 min (fig. 4). However, close inspection of figure 1 reveals that, after the initial hypertension, SAP showed a trough at 9–16 min and then drifted back up above the reference level. As SAP was in part inversely dependent on end-tidal partial pressure, this upward drift in SAP can explain some of the decline in *P*E'bi.

Can the findings of Couto da Silva[5–8] be replicated in a double-blind study?

The findings that the doses of enflurane required were less than predicted, and that recovery from enflurane was more rapid than that from halothane or isoflurane were confirmed (tables 2, 4) and the study was mostly blind: although the anaesthetist usually identified halothane (table 6), it generally took approximately 25 min to form a firm opinion so that the first five or six injections of halothane (half the average total number) were made blind, as were all injections of enflurane and isoflurane.

Can the cause of the discrepancy between agents be elucidated?

Compared with halothane and isoflurane, enflurane required approximately 50% of the dose (as a fraction of predicted) (upper part of table 2), and produced approximately half the steady-state *P*E'bi (in MAC units) (table 3). Therefore, either the MAC of enflurane is less than previously believed or patients who received enflurane were more lightly anaesthetized.

The time taken to reach each of the four stages of recovery was only approximately 50% as long with enflurane as with halothane or isoflurane (table 4), and memories of preoperative events were greater with enflurane, although this was not significant (table 5). Therefore, it must be concluded that patients receiving enflurane were less deeply anaesthetized. As administration of all agents was based mainly on maintenance of the reference SAP, it must also be concluded that, at any given MAC level, enflurane is a more potent hypotensive agent than halothane or isoflurane. These conclusions are supported by other studies in different circumstances.[23–27]

Does the Lowe technique produce satisfactory anaesthesia?

Despite the inevitable sawtooth pattern of end-tidal partial pressure (fig. 3), SAP decreased by only 3–4 mm Hg, on average, as a result of each injection. Also, after an initial hypertension (fig. 1), 86% of all measurements were within the target range (reference SAP ±20%).

The overall incidence of cardiac rhythm disturbances (43%) was less than the "60% or more" quoted by Atlee[28] as common, although marginally greater (70%) with halothane. However, these disturbances generally appeared as a new dose became due (and partial pressure was at a minimum) and disappeared soon afterwards.

Mean steady-state *P*E'bi was less than the MAC for all three anaesthetics (table 3) (less than 50% of the MAC for enflurane) and the four stages of recovery were reached in times that were very short (table 4) compared with those reported for recovery to the same four stages from halothane and nitrous oxide anaesthesia.[11] However, no patient admitted to any dreams and all were prepared to have the same type of anaesthetic again.

We conclude that anaesthesia was indeed satisfactory although we suggest some improvements below.

LIMITATIONS OF THE PRESENT STUDY

Errors in the measurement of anaesthetic partial pressure

The Normac, in common with some other multi-gas monitors, measures all volatile anaesthetics by infrared absorption at 3.3 μm. Therefore, interference from "foreign" gases and vapours is possible, particularly with a closed system in which such gases may accumulate, and especially when measuring halothane for which the analyser gain is set approximately five times greater than for enflurane or isoflurane. Generally, this does not appear to be a serious problem but two recent studies from Belgium[29 30] have shown methane accumulating at approximately 700 ppm per hour leading to apparent halothane concentrations (measured at 3.3 μm) increasing by approximately 0.7% per hour.

In this study, halothane was unique in showing a positive drift in partial pressure (after 49 min) but the drift was not significant (0.04% per hour) and so of negligible importance. As methane is produced by microbial fermentation of carbohydrates, mainly in the distal colon,[30] the difference from patients in Belgium may perhaps be related to a difference in gut flora or diet.

Differences between end-tidal and arterial partial pressure

Lowe's theory is based on arterial partial pressures; we measured end-tidal partial pressures. The former must have been less than the latter throughout our study because of continuing uptake: even just before the last dose, inspired partial pressure was always a little greater than end-tidal. However, virtually all MAC values are based[12] on measurements of end-tidal partial pressure. Therefore, our *P*E'bi values expressed in MAC units should be consistent with those in other studies.

Leakage rate

The outflow from the Normac analyser includes a small flow of air (30 ml min^{-1} in our analyser) drawn in as a reference gas. The nitrogen content of this air (24 ml min^{-1}) forms a convenient tracer gas from which leakage can be calculated. First, after approximately 2 h, oxygen concentration in the breathing system reached a plateau (60% on average). Therefore, at that time, the inflow of nitrogen must have equalled the outflow, and nitrogen excretion from the body would by then be negligible. Accordingly, the 24 ml min^{-1} from the Normac formed 40% of the leakage rate. Therefore, total leakage was approximately 60 ml min^{-1} and included approximately 36 ml min^{-1} of oxygen.

LIMITATIONS AND IMPROVEMENTS OF THIS METHOD OF ANAESTHESIA

Although 30 of 90 patients were excluded, in only six instances were the causes relevant to clinical use of the technique: five of these were leaks (only one of which led to abandonment of the closed system) and one was use of adrenaline by the surgeon which interfered with judgement of depth of anaesthesia. Therefore, the technique is widely applicable.

The instance of adrenaline use draws attention to a general problem in using arterial pressure as a main measure of depth of anaesthesia: any drug, or other event, that has a direct effect on arterial pressure but not on depth of anaesthesia must be avoided, or allowed for, or another method of assessing depth must be used.

In routine clinical practice, anaesthesia could be deepened rapidly or lightened at any time by an extra injection or by opening the system, or even by inserting a charcoal absorber.[31] However, the need did not arise in any of the 90 patients entered into this study.

We used a short-acting non-analgesic induction agent (etomidate) and no opioid, to ensure minimum interference with comparison of the volatile agents. Therefore, in routine clinical practice, the initial hypertension could be reduced by using more appropriate drugs and reducing the early doses of liquid anaesthetic correspondingly.

An enflurane PE'bi value of 0.42 MAC obviously raises concerns about awareness, even though MAC-awake (the concentration at which the patient just responds to command) has been reported to be 0.27 MAC for enflurane.[32] In this respect, it is important to note that the zero incidence of awareness found in our 20 patients implies that the upper 95% confidence limit, for the incidence in a population anaesthetized in the same way, would be three in 20 (15%).[33] Accordingly, if enflurane is to be used with this technique, it may be advisable to aim for an SAP which is less than the reference value.

Age- and sex-standardized tables of SAP[34] have been used[35] as a basis for a reference SAP, but the differences of our reference SAP values from those derived from these tables had a mean of −3.4 mm Hg and an SD of 14 mm Hg. Therefore, the effort of taking the time to obtain a valid reference SAP for each patient may be repaid.

A common concern with closed-system anaesthesia is that carbon monoxide may accumulate. A recent study[36] showed that this arose from degradation of several volatile anaesthetics by the carbon dioxide absorbent, especially when this was dry. However, although we flushed the soda lime with 6 litre min^{-1} of oxygen overnight, blood carboxyhaemoglobin increased on average only by 0.2% (ns) with an upper confidence limit of 0.4% and an SD of 0.8%.

RECOMMENDATIONS

The Lowe intermittent-injection square-root-of-time method of closed-system anaesthesia provides the basis of a simple, economic method of anaesthesia. The calculated unit dose can be used as a guide, but the choice of individual doses in each patient must depend on the skill of the anaesthetist in assessing depth of anaesthesia. If this assessment is based mainly on maintaining a normal SAP, the resulting end-tidal partial pressures are likely to be much less than 1.3 MAC, especially for enflurane, where it may be advisable to aim for perhaps 10% less than the preoperative value.

REVIEW ARTICLE

Thorascopic sympathectomy in the treatment of palmar hyperhidrosis: anaesthetic implications

B. FREDMAN, D. OLSFANGER AND R. JEDEIKIN

As a result of technical advances, endoscopic surgery has become the technique of choice for many intra-abdominal and thoracic surgical procedures. The advantages of endoscopic surgery include less postoperative pain, shorter hospital admission, earlier return to normal activity and improved cosmetic result.[15 17 19 54]

Thorascopic surgery differs from other endoscopic procedures in that adequate surgical exposure requires collapse or retraction of the operative lung. Whether achieved by one-lung ventilation or carbon dioxide insufflation, these interventions may be associated with significant cardiorespiratory disturbances.

In this review thorascopic sympathectomy in the treatment of palmar hyperhidrosis and related controversies are discussed. Special emphasis is placed on the anaesthetic considerations of this procedure. Finally, based on our clinical experience, recommendations are made regarding the anaesthetic of choice.

Palmar hyperhidrosis

Primary palmar hyperhidrosis (sweating that exceeds that needed for thermoregulation) is a rare condition of unknown aetiology which has an estimated incidence of 0.6–1.0%.[1] Occurring mostly in otherwise healthy adolescents, this condition is usually bilateral, characterized by excessive sweating, often affecting the palms of the hands, axillae and feet. While moist axillae and feet cause considerable discomfort, wet or dripping hands result in serious functional disability with consequent social and psychological handicaps.[44]

Drug therapy,[50] biofeedback,[20] iontophoresis[34] and percutaneous phenol block[16] have been attempted. However, medical treatment of palmar hyperhidrosis appears to be successful only in the mildest of cases.[11] In contrast, surgical ablation of the upper thoracic sympathetic chain is associated with excellent results. Therefore, in view of the poor results associated with medical therapy, surgical intervention has become the treatment of choice in the primary management of hyperhidrosis.[10 14 32 38]

Surgical approach: open *vs* thorascopic

As the upper thoracic sympathetic chain is relatively inaccessible, open surgical sympathectomy was traditionally performed. This was done usually via the supraclavicular,[53] axillary[5] or posterior approach.[3] However, none of these procedures is simple and all carry some risk of complications. In a retrospective study of 475 patients who underwent open supraclavicular sympathectomy, early postoperative complications included transient Horner's syndrome (12%), pneumothorax (6%) and pleural effusion (4%). Compensatory sweating (80%), gustatory phenomena (75%), phantom sweating (53%), respiratory discomfort (22%) and wound pain (12%) occurred as late postoperative sequelae.[1] Because of these early and delayed complications, surgeons have been reluctant to perform open sympathectomy when treating a non-life threatening condition such as hyperhidrosis.

The introduction of thorascopic electrocauterization of the sympathetic chain by Kux[32] has significantly simplified the procedure and resulted in an increased interest in both palmar hyperhidrosis and its surgical treatment. Gothberg, Drott and Claes[23] reported excellent results after 1274 thorascopic sympathectomies in 602 patients. The procedure was successful in 99% of patients with delayed recurrence of symptoms occurring in 0.8% of cases. One case of Horner's syndrome was reported. The incidence of pneumothorax and haemothorax were 0.4% and 0.15%, respectively. Furthermore, patient-generated visual analogue pain scores demonstrated minimal postoperative pain.[23] We speculate that the high complication rate (Horner's syndrome, pneumothorax, pleural effusion) associated with open sympathectomy is the result of local tissue damage during surgical dissection. Specifically, supraclavicular dissection may result in inadvertent trauma to the stellate ganglion with consequent transient or permanent

(*Br. J. Anaesth.* 1997; **79**: 113–119).

Key words
Surgery, thoracic. Surgery, endoscopy. Complications, palmar hyperhidrosis.

Horner's syndrome.[1] In contrast, during thorascopic sympathectomy the surgical field is easily seen with little associated tissue trauma.

Unfortunately, there are few randomized, prospective studies comparing overall patient outcome and complication rates between the two surgical procedures. In a prospective, randomized study of 24 patients allocated to undergo either bilateral open supraclavicular thoracic sympathectomy or bilateral thorascopic sympathectomy, Hashmonai, Kopelman and Schein demonstrated prolonged postoperative pain in the thorascopic group. However, no other differences were found between the two treatment modalities.[27] The differences between these findings and those of Gothberg, Drott and Claes[23] may be a result of the length of the surgical procedure (157 min *vs* 25 min). However, the exact mechanism of this pain is unclear. Our clinical experience correlates with the minimal postoperative pain reported by Gothberg, Drott and Claes.[23]

Both open and thorascopic sympathectomy may be complicated by postoperative compensatory hyperhidrosis of the torso, buttocks and thigh. However, the incidence of this condition after thorascopic sympathectomy requires further investigation. While the exact pathophysiology of this condition is unclear, it has been suggested that compensatory sweating is caused by a centrally mediated abnormality of thermoregulation and sudomotor function.[2 13 49] Compared with the preoperative condition, compensatory hyperhidrosis is usually mild.

Preoperative preparation

Patients should be well counselled and fully understand the procedure, its success rate and the possibility of transient postoperative chest pain and delayed compensatory sweating. As the majority of patients undergoing thorascopic sympathectomy are young and otherwise healthy adolescents, this procedure is ideally suited to "same day" admission. Following recent advances in preoperative evaluation, unless specifically indicated by history and physical examination, no laboratory investigations are necessary.[47]

In our experience the only cost effective preoperative investigation is a baseline chest x-ray. This is useful in the preoperative diagnosis of pulmonary adhesions and when evaluating possible postoperative pulmonary pathology.

Depending on physician and patient preference, either no premedication or a short-acting benzodiazepine should be administered.[43]

Anaesthetic technique

As the thoracic sympathetic chain lies on the posterior chest wall and is hidden by the lung parenchyma, the ipsilateral lung must be either collapsed or retracted to facilitate adequate surgical exposure. This may be performed via endobronchial anaesthesia or by carbon dioxide insufflation in combination with a tracheal tube. Recently, the use of a laryngeal mask airway (LMA) and face mask anaesthesia have also been reported. These fundamental differences in anaesthetic technique make prospective, randomized, double-blind studies difficult to perform.

Irrespective of the anaesthetic technique, unless specifically contraindicated (unilateral symptoms, pulmonary adhesions), bilateral sympathectomy is performed.

ENDOBRONCHIAL ANAESTHESIA

Endobronchial anaesthesia provides excellent surgical conditions and is associated with a low risk of surgically induced injury to the lung, stellate ganglion and major thoracic blood vessels.

Having placed the endobronchial tube the patient's arms are abducted to 90°. Thereafter, the tube is opened to the atmosphere and the ipsilateral lung is collapsed in order to separate the parietal from the visceral pleura. This procedure prevents lung injury when the Verres' needle, trocar and endoscope are inserted. However, confirmation of tube positioning by observation and auscultation is time consuming and not always reliable.[6 51] While fibreoptic laryngoscopy may be performed,[8] this procedure requires sophisticated equipment and its reliability is operator dependent. Incorrect placement of the double-lumen tube may result in failure of the ipsilateral lung to "fall away" with consequent instrument-induced lung injury.

During endobronchial anaesthesia carbon dioxide insufflation augments lung collapse and therefore provides additional lung protection during insertion of the endoscopic instruments. Thereafter, collapse of the entire lung is accomplished and maintained by the endobronchial tube and carbon dioxide insufflation plays no part in facilitating surgical exposure.

ANAESTHESIA USING A TRACHEAL TUBE

Anaesthesia with a tracheal tube has many advantages compared with the endobronchial technique (table 1). The tracheal tube is quickly and easily placed, and requires no special expertise or equipment to confirm correct placement. Furthermore, the tracheal tube is significantly less expensive compared with the endobronchial tube.

Table 1 Advantages and disadvantages of anaesthesia with a tracheal tube compared with the endobronchial technique. PHV=Pulmonary hypoxic vasoconstriction. Because of insufficient data at time of publication the advantages and disadvantages of LMA and face mask anaesthesia have been omitted

Advantages	Disadvantages
Endobronchial technique	
Low incidence of tissue injury	Confirm tube position
No accidental re-expansion	Abolish PHV
Tracheal tube	
Quick, easy tube placement	Possible lung injury
No abolition of PHV	Surgical field insufflator dependent
Improved oxygenation	Transient hypotension following positioning
Less expensive	Possible tension pneumothorax

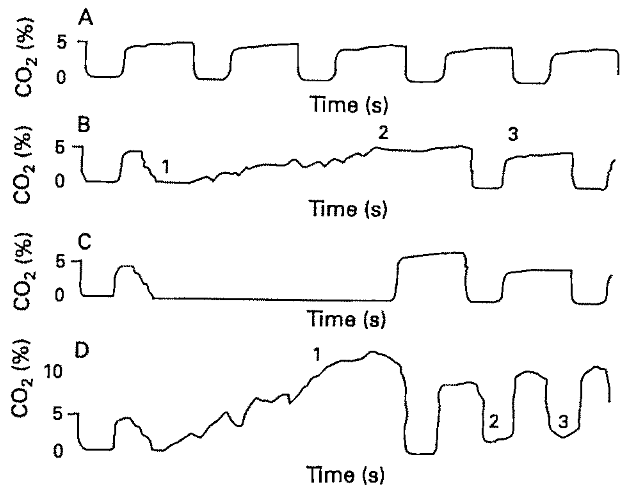

Figure 1 Diagrammatic representation of the capnograph waveform seen during thorascopic sympathectomy with anaesthesia using a tracheal tube. A: Normal, both lungs ventilated. B: Correct placement of the Verres' needle in the intrapleural space is confirmed; ventilation stopped, expiratory valve opened to the atmosphere, expired carbon dioxide concentration decreases to zero (point No. 1); 0.5 litre of carbon dioxide insufflated through the Verres' needle partially collapses the lung and expired carbon dioxide concentration gradually returns to 4–5% (point No. 2); lung ventilation resumed, normal waveform during additional 0.5–1.5 litre of carbon dioxide insufflation (point No. 3). C: Verres' needle in chest wall of pleural adhesions prevents lung collapse; no increase in expired carbon dioxide concentration from zero during insufflation. D: Lung puncture; during insufflation expired concentration of carbon dioxide increases to about 8–12% (point No. 1), on resumption of ventilation end-inspired concentration does not return to zero but increases with each ventilation (point Nos 2 and 3). (Reprinted from *British Journal of Anaesthesia* 1995; 74: 141-144.)

Despite these advantages a clear understanding of the potential pitfalls is essential in order to maintain the operative field and prevent respiratory and haemodynamic complications.

After induction of general anaesthesia, in order to prevent Verres' needle-induced lung injury, immediately before inserting the needle, apnoea is induced and the expiratory valve opened to the atmosphere. The Verres' needle is then inserted into the pleural space via a small incision in the fourth intercostal space, midaxillary line and the lung partially collapsed and compressed by insufflating 0.5 litre of carbon dioxide. The end-tidal carbon dioxide tracing must be interpreted carefully in order to verify placement of the Verres' needle and exclude accidental lung puncture (fig. 1).

In contrast with endobronchial anaesthesia, when using a tracheal tube carbon dioxide is insufflated continuously into the intrapleural space until the end of surgery. This is achieved by using a variable flow carbon dioxide insufflator. The resultant continuous positive intrapleural pressure, together with placement of the patient in the semi-sitting position, provide adequate exposure of the upper thoracic cavity.

A disadvantage of the tracheal tube technique is that when intrapleural pressure decreases, the ipsilateral lung rapidly re-inflates and obstructs the surgical field. This may be produced by cessation of carbon dioxide insufflation, leak from the delivery system or use of excessive intrapleural suction to control bleeding.

LARYNGEAL MASK AIRWAY AND FACE MASK ANAESTHESIA

In a non-English study, the efficacy of a laryngeal mask airway (LMA) was compared with a double-lumen endobronchial tube and arterial oxygen saturation (Sp_{O_2}) was shown to be significantly ($P<0.001$) improved in the LMA group. However, as total lung collapse is associated with ventilation–perfusion ($\dot{V}/\dot{Q}$) mismatch and shunting, it is not surprising that two-lung ventilation via an LMA resulted in improved patient oxygenation.[28]

In a similar study, Lieou and colleagues administered total i.v. anaesthesia with a neuromuscular blocking agent to 198 patients undergoing thorascopic sympathectomy. In all cases the airway was maintained using a tight fitting face mask and ventilation assisted. Throughout the procedure mean Sp_{O_2} and end-tidal carbon dioxide were 99% and 36%, respectively.[35]

While these studies represent a deviation from the traditional practice of intubation and controlled ventilation, language limitations make critical analysis difficult.

Special considerations

HYPOXAEMIA

Hypoxaemia is of major concern during thorascopic sympathectomy. However, the pathophysiology of hypoxaemia and consequent decrease in Sp_{O_2} differs between the two anaesthetic techniques.

Endobronchial intubation

The normal physiological response to massive atelectasis is an increase in pulmonary vascular resistance (hypoxic pulmonary vasoconstriction) with re-routing of blood to well ventilated lung zones and consequent improvement in Pa_{O_2}. However, during endobronchial anaesthesia for thoracic sympathectomy there is apparent failure of this compensatory mechanism. When more than 70% of the lung is atelectatic, compensation by hypoxic pulmonary vasoconstriction appears to be ineffective.[37] Furthermore, in *in vitro*[9] and animal studies,[7] inhalation anaesthetic agents have been shown to depress hypoxic pulmonary vasoconstriction. However, these findings have not been confirmed in clinical studies where 1 MAC of either halothane or isoflurane was administered.[46]

In a study of 101 sympathectomies in 58 patients, despite administration of 100% oxygen, Sp_{O_2} was 99–100% in 32 patients, 95–98% in 21 patients and in three patients an Sp_{O_2} value of less than 95% was recorded.[30] Furthermore, in a study by Hartrey and colleagues, Sp_{O_2} <95% was demonstrated in 74% of cases receiving an FI_{O_2} of 0.5.[26] This $\dot{V}/\dot{Q}$ mismatch and shunt effect was confirmed when arterial blood-gas measurements were made during one-lung ventilation and compared with baseline values during two-lung ventilation. In 25% of sympathectomies studied, Pa_{O_2} <15 kPa was recorded. It should be remembered that after re-inflation of the collapsed lung, $\dot{V}/\dot{Q}$ mismatch may be persistent and that time is required for the lung to recover its full oxygenation capacity.[29 45] This problem period has been managed successfully with high frequency jet ventilation while administering 100% oxygen.[24]

During endobronchial anaesthesia, use of continuous positive airway pressure (CPAP) ventilation has been advocated for the treatment of hypoxia associated with one-lung ventilation.[12 40] However, this interferes with surgical exposure and often re-insufflation of carbon dioxide is required before proceeding with surgery. Alternatively, significant intraoperative hypoxaemia has been shown to be corrected easily by administering one or two gentle ventilations to the collapsed lung. This procedure promptly improves Sp_{O_2} without interfering with the surgical field.[29]

Tracheal tube

Compared with the endobronchial technique, during anaesthesia with a tracheal tube continuous positive intrapleural pressure results in a reduction in the transpulmonary pressure gradient across the operative lung. Therefore, a greater percentage of the ventilator generated tidal volume enters the contralateral lung. Furthermore, as the lung is only partially collapsed, pulmonary hypoxic vasoconstriction remains intact and thus contributes to the improved oxygenation associated with anaesthesia with a tracheal tube.[41]

In a study of 719 cases undergoing anaesthesia with a tracheal tube for transthoracic electrocautery of the sympathetic chain, Lee, Seok-Mun and Lin administered 100% oxygen in combination with isoflurane and reported an Sp_{O_2} >99% throughout the operative procedure.[33] However, administration of 30% inspired oxygen in nitrous oxide resulted in an Sp_{O_2} of 93–96%. By increasing FI_{O_2} to 0.4–0.5, Sp_{O_2} stabilized to >98% in all patients.[41] Therefore, we suggest an initial FI_{O_2} of 0.4%, careful oximetric monitoring and adjustment of the inspired oxygen concentration to maintain an Sp_{O_2} >98%.

CARBON DIOXIDE INSUFFLATION

Rapid and excessive carbon dioxide insufflation into the closed chest cavity may create a tension pneumothorax, displace the mediastinum, and compress the lungs and great vessels with consequent haemodynamic instability. During carbon dioxide insufflation using endobronchial intubation, Hartrey and colleagues[26] reported a decrease in systolic arterial pressure of >20 mm Hg in 21% of patients. Similarly, we have reported sudden hypotension and bradycardia after injudicious carbon dioxide insufflation.[30] Therefore, both the anaesthetist and surgeon should be aware of this complication and excessive carbon dioxide insufflation avoided. Irrespective of the technique used, insufflation of up to 1 litre is usually sufficient to collapse the ipsilateral lung without inducing unwanted adverse effects.[41]

After accidental Verres' needle-induced lung puncture, carbon dioxide is insufflated directly into the lung parenchyma and bronchi. As the insufflation rate is greater than the predicted carbon dioxide production during uncomplicated anaesthesia,[39] this is readily diagnosed from the capnogragh waveform (fig. 1) and end-tidal carbon dioxide concentration.[41]

CARDIAC COMPLICATIONS

Although extremely rare, sudden cardiac arrest has been reported after left T2–3 sympathetic nerve transection. While the exact pathophysiology of this occurrence is unclear, it is postulated that before complete transection of the sympathetic trunk, continuous sympathetic stimulation to the stellate ganglions results in a reduction in the ventricular fibrillation threshold, arrhythmia and consequent cardiac arrest.[36]

In an interesting study of the delayed cardiac effects of T2–4 sympathectomy, Drott and colleagues demonstrated significantly reduced heart rate at rest, and during both exercise and the recovery phase of exercise. While systolic arterial pressure was reduced similarly, there was no significant reduction in diastolic arterial pressure.[18] Changes in the electrical axis and shortening of the QT interval have also been reported.[42] These results formed the basis for surgical cardiac sympathetic denervation in selected patient populations.[55]

Anaesthetic drug administration

Thoracoscopic electrocauterization of the sympathetic chain is usually an extremely short procedure. Therefore, anaesthetic drugs administered should be potent and short acting with few associated unwanted side effects. While inhalation anaesthetic agents are cheap and easy to administer, total i.v. anaesthesia with propofol has the theoretical advantage of not attenuating hypoxic vasoconstriction during one-lung ventilation.[21] Using a tracheal tube and total i.v. anaesthesia with propofol, alfentanil and atracurium in combination with 40% oxygen in air, no significant decrease in Sp_{O_2} was noted during carbon dioxide insufflation and partial collapse of the ipsilateral lung.[25] However, these positive finding are possibly FI_{O_2} dependent and not related to propofol administration.

Our anaesthetic of choice includes i.v. administration of fentanyl 5–7 $\mu g\ kg^{-1}$, propofol 1–2 mg kg^{-1} and atracurium 20–40 mg for induction of general anaesthesia. Thereafter, anaesthesia is maintained with 0.5–1.0 MAC of isoflurane and 50–60% nitrous oxide in oxygen. On conclusion of the surgical procedure the anaesthetic agents are discontinued, 100% oxygen administered and residual neuromuscular block antagonized with neostigmine and atropine.

Monitoring

In common with other surgical procedures, routine monitoring during thoracoscopic sympathectomy should include ECG, pulse oximetry and capnograghy. However, during thoracoscopic surgery, Sp_{O_2}

and end-tidal carbon dioxide have the additional function of monitoring the surgical technique.

Failure to observe an increase in end-tidal carbon dioxide during the insufflation phase indicates that the Verres' has been placed incorrectly. Furthermore, accidental lung puncture by the Verres' needle is easily recognized by a sudden steep increase in end-tidal carbon dioxide and from the classic waveform seen on the capnograph monitor (fig. 1). Finally, a sudden decrease in end-tidal carbon dioxide during carbon dioxide insufflation should raise suspicion of insufflator-induced tension pneumothorax and consequent decrease in pulmonary blood flow.[41]

As thorascopic sympathectomy is always associated with lung collapse and consequent $\dot{V}/\dot{Q}$ mismatching, pulse oximetry is mandatory during this procedure. Early diagnosis and adequate management of hypoxaemia during one-lung ventilation or after re-inflation of the operative lung requires both vigilance and ability to titrate FI_{O_2} against monitored Sp_{O_2}.

Postoperative care

The major postoperative concerns include exclusion of residual pneumothorax and haemothorax, and adequate treatment of postoperative pain (table 2). In the majority of cases the postoperative period is uneventful and after an overnight admission patients are routinely discharged. As clinical decisions are often based on radiological findings, postoperative chest x-ray is mandatory.

Irrespective of the technique used the reported incidence of postoperative pneumothorax is variable, occurring in 2–15% of cases.[48] As the lung is re-inflated under direct vision and the endoscope removed only when the lung is seen to bulge into it, this variability is probably technique dependent. In cases where residual pneumothorax is diagnosed, the extent of lung collapse should determine the need for intercostal drain. In a study by Gothberg, Drott and Claes,[23] postoperative chest x-ray after 1274 procedures in 602 patients demonstrated that a small apical pneumothorax (5±1 mm) was a usual occurrence. However, in only 0.8% of cases, because of expanding pneumothorax, was overnight chest drainage instituted. In our experience as most pneumothoraces are small, the decision to insert a chest drain depends on specific patient and physician tolerance and radiological evidence of expansion.

Haemothorax appears to be a relatively rare occurrence and is usually diagnosed by a combination of clinical signs and postoperative chest x-ray findings (table 2). Management decisions are patient specific.

Postoperative pain is common and most severe in the first 2–4 h after operation. As pain is generally retrosternal or in the upper back region and is not related to the incision, the exact mechanism is unclear. It has been suggested that carbon dioxide insufflation and consequent displacement of the mediastinum results in stretching of the pleura and activation of pain pathways.[22] While pain is adequately managed by postoperative opioid administration,[33,48] intrapleural catheters and local anaesthetic injection have had some success.[22,33] However, because of the possible danger of bilateral phrenic nerve block,[4] intrapleural local anaesthetic agents should be administered cautiously.[31] Non-steroidal anti-inflamatory drugs (NSAID) may provide an attractive alternative to opioids in the treatment of post-thoracospy pain. However, because of their slow onset of action, variable efficacy[52] and short duration of endoscopic sympathectomy, we have been unimpressed by NSAID-induced analgesia after endoscopic sympathectomy.

Table 2 Postoperative complications after anaesthesia with a tracheal tube compared with the endobronchial technique

Reference	Anaesthetic technique	Complication	Incidence/Cases performed
Jedeikin and colleagues[31]	Endobronchial	Pneumothorax, no ICD	8/58
		Haemothorax and ICD	2/58
		Subcutaneous emphysema	2/58
		Transient Horner's	2/58
Drott and colleagues[18]	Tracheal tube	Pneumothorax	5/535
		Haemothorax and ICD	1/535
		Postop. bradycardia	2/18
		Systolic arterial pressure	1/18
Hartrey and colleagues[26]	Endobronchial	Hypotension	
		Lung collapse	10/26
		Lung expansion	8/26
		Pneumothorax and ICD	2/26
Shachor and colleagues[48]	Endobronchial	Pneumothorax, no ICD	5/150
		Pneumothorax and ICD	2/150
		Haemothorax	3/150
		Subcutaneous emphysema	8/150
		Transient Horner's	2/150
Lee and colleagues[36]	Tracheal tube	Pneumothorax and ICD	1/719
		Haemothorax and ICD	7/719
		Scrotal emphysema	1/719
Lin and colleagues[36]	Tracheal tube	Cardiac arrest	2/719
Olsfanger and colleagues[41]	Tracheal tube	Hypotension	3/79
		Lung puncture	6/79
		Pneumothorax and ICD	3/79
		Haemothorax and ICD	2/79

In our experience adequate intraoperative analgesia significantly reduces the troublesome problem of postoperative pain and analgesic requirements.

Conclusion

Because of the anaesthetic implications and possible surgical complications, many surgeons are reluctant to perform transthoracic sympathectomy. However, this fear is poorly supported by the literature. Both in our experience, and from published data, it would appear that this procedure is safe and effective for treating palmar hyperhidrosis.

With the introduction of anaesthesia using a tracheal tube and use of a variable flow carbon dioxide insufflator, intraoperative airway management has been simplified and the incidence of hypoxia associated with one-lung ventilation decreased.

In conclusion, thorascopic sympathectomy is a simple and easy procedure associated with little cosmetic morbidity and few postoperative complications. Furthermore, in an era of soaring medical expenditure this procedure has the additional advantages of providing bilateral relief of the disabling symptoms while requiring few preoperative investigations, a "same day" admission and short hospital stay.

SHORT COMMUNICATIONS

Extradural buprenorphine suppresses breast feeding after Caesarean section

M. HIROSE, T. HOSOKAWA AND Y. TANAKA

Summary

Satisfactory pain relief with postoperative extradural bupivacaine increases the amount of breast feeding after Caesarean section. To investigate the effect of extradural buprenorphine, we have evaluated the amount of breast feeding and the gain in infant weight for 11 days after Caesarean section in patients who received continuous extradural bupivacaine with or without buprenorphine. Extradural buprenorphine significantly decreased both measures although there was no significant difference in pain intensity. We suggest that extradural buprenorphine suppressed breast feeding after Caesarean section. (*Br. J. Anaesth.* 1997; **79**: 120–121).

Key words
Anaesthesia, obstetric. Analgesic techniques, extradural. Analgesics opioid, buprenorphine. Pain, postoperative.

Our recent investigation revealed that satisfactory postoperative pain relief with continuous extradural bupivacaine for 3 days after Caesarean section improved the amount of breast feeding and gain in infant weight compared with unsatisfactory pain relief without extradural analgesia.[1] Although extradural opioids are also known to provide satisfactory analgesia after Caesarean section,[2 3] the effect of extradural opioids on breast feeding has not been evaluated. Extradural bupivacaine has less effect on the neurobehavioural state of the neonate than other local anaesthetics or opioids.[4 5] Opioids such as pethidine[6] induce neurobehavioural depression in the neonate. We hypothesized that extradural opioids would suppress breast feeding while providing satisfactory postoperative pain relief. To evaluate the effect of extradural buprenorphine, we measured the amount of breast feeding and gain in infant weight for 11 days in patients who received continuous extradural bupivacaine with or without buprenorphine for 3 days after Caesarean section.

Methods and results

After obtaining approval from the hospital Ethics Committee and written informed consent, we studied two groups of full-term parturients (without co-existing disease) who had undergone elective Caesarean section under spinal and extradural anaesthesia. Indications for Caesarean section were previous Caesarean section, breech presentation and predicted cephalopelvic disproportion. Patients were allocated randomly to one of two groups to receive extradural bupivacaine alone (control group, $n=10$) or extradural bupivacaine and buprenorphine (buprenorphine group, $n=10$) for postoperative pain management.

All patients were premedicated with metoclopramide 10 mg i.v., 1 h before operation. After the patient received an i.v. infusion of lactated Ringer's solution 1–1.5 litre, the extradural catheter was placed at the T12–L1 or L1–2 interspace, and then 0.3% cinchocaine 1.2–1.8 ml was given intrathecally using a 26-gauge disposable spinal needle into the L3–4 or L4–5 interspace. In the control group, patients were given 0.25% bupivacaine 5 ml extradurally as a loading dose after clamping of the umbilical cord, followed by continuous infusion of 0.25% bupivacaine 0.7 ml h^{-1} using a disposable balloon-operated infuser (Sure-fuser SFA-0503D, Nipro, Japan) for 3 days for pain relief. In the buprenorphine group, patients were given 5 ml of 0.25% bupivacaine with buprenorphine 200 μg extradurally after clamping of the umbilical cord, followed by continuous infusion of 0.25% bupivacaine 0.7 ml h^{-1} containing buprenorphine 12 μg ml^{-1}. Diclofenac suppository 25 mg was available on demand for supplementary analgesia in both groups.

All patients started breast feeding when they were able to assume a sitting position after operation, and were encouraged to nurse every 4 h. The weight of milk fed by breast and infant weight were measured for 11 days. To measure the weight of milk fed by breast, each mother weighed her baby on the scales before and after nursing. All babies wore a nappy during nursing to prevent underestimation of the weight caused by urination. Pain intensity both at rest and at coughing was assessed using a visual analogue scale (0 cm=no pain, 10 cm=worst imaginable pain) at three times: 2 h after operation, 1 and 2 days in the morning after operation.

Two-way ANOVA for repeated measures was used for inter-group comparisons. After testing

MUNETAKA HIROSE, MD, TOYOSHI HOSOKAWA, MD, YOSHIFUMI TANAKA, MD, Department of Anaesthesiology, Kyoto Prefectural University of Medicine, Kamigyoku, Kyoto 602, Japan. Accepted for publication: March 4, 1997.

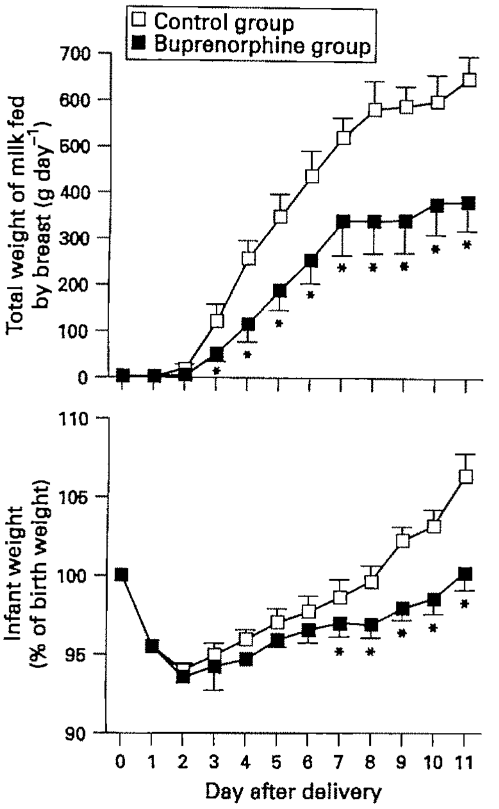

Figure 1 Time course of the extent of breast feeding and change in infant weight, expressed as a percentage of birth weight, after delivery. Patients in the control group (n=10) received postoperative pain management with extradural bupivacaine and patients in the buprenorphine group (n=10) received extradural bupivacaine and buprenorphine. Data are mean (SEM). *Significantly different from corresponding value in the control group.

significant differences, Fisher's least significant difference test was used to identify significant differences in various pairs of comparisons. The null hypothesis was rejected when $P<0.05$. All values are reported as mean (SEM).

There were no differences in age, weight or height of parturients, or neonatal birth weight. Number of primiparous/multiparous women was 7/3 in the control group and 6/4 in the buprenorphine group. All multiparous women had previously breast fed successfully. Apgar scores in all neonates at 1 and 5 min were 8–10. Visual analogue scale scores 2 h, 1 and 2 days after operation at rest were: 15.6 (8.2), 15.0 (5.3) and 9.3 (4.4) mm in the control group and 16.0 (6.0), 7.4 (3.8) and 4.1 (2.9) mm in the buprenorphine group. Visual analogue scale scores on coughing were 23.8 (9.8), 36.7 (8.9) and 32.0 (8.6) mm in the control group and 16.0 (7.3), 33.2 (5.1) and 27.5 (7.5) mm in the buprenorphine group. There were no significant differences in scores between the groups. Total dose of diclofenac for 3 days after operation in the buprenorphine group was 5 (5) mg, which was significantly less than that in the control group (25 (8) mg). In the control group, five patients required diclofenac compared with one patient in the buprenorphine group. Both the extent of breast feeding and gain in infant weight were significantly suppressed in the buprenorphine group compared with the control group (fig. 1).

Comment

We found that extradural buprenorphine added to bupivacaine decreased both the weight of milk fed by breast and gain in infant weight compared with extradural bupivacaine alone, even though it provided satisfactory pain relief and reduced the dose of supplementary analgesics. Buprenorphine, a highly lipid-soluble opioid partial agonist, can easily cross the lipid membrane in the mammary gland from the intravascular space and can affect not only the maternal but also the neonatal central nervous system. We suggest that extradural buprenorphine suppressed breast feeding. Further study is needed to evaluate the effect of other extradural opioids, such as morphine, fentanyl and pethidine, on breast feeding after Caesarean section.

Postoperative pain relief for only 3 days affects breast feeding for up to 11 days after Caesarean section.[1] This study also showed that the effect of extradural buprenorphine for 3 days on breast feeding continued for up to 11 days after Caesarean section. Therefore, maternal postoperative pain relief after Caesarean section could be an important factor in infant development.

Administration of magnesium sulphate before rocuronium: effects on speed of onset and duration of neuromuscular block

B. KUSSMAN, G. SHORTEN, J. UPPINGTON AND M. E. COMUNALE

Summary

The speeds of onset of pancuronium, atracurium and vecuronium are increased by prior administration of magnesium sulphate. A prospective, randomized, double-blind, controlled, clinical study was performed to examine the effects of prior i.v. administration of magnesium sulphate 60 mg kg^{-1} on the neuromuscular blocking effects of rocuronium 0.6 mg kg^{-1} during isoflurane anaesthesia. Neuromuscular function was measured electromyographically (Relaxograph) in 30 patients who received either magnesium sulphate 60 mg kg^{-1} or normal saline, 1 min before rocuronium 0.6 mg kg^{-1}. Mean onset times were similar in the two groups (magnesium sulphate 71 (SD 20) s; normal saline 75 (23) s), but times to initial, 10% and 25% recovery from neuromuscular block were significantly longer in the magnesium sulphate group (42.1 (16.3), 49.0 (12.4) and 56.5 (13.2) min, respectively) than in the saline group (25.1 (9.1), 33.0 (11.1) and 35.6 (13.2) min, respectively) ($P<0.05$ in all three cases). Administration of magnesium sulphate was not associated with adverse haemodynamic effects. Prior administration of magnesium sulphate, under the study conditions described, prolonged rocuronium-induced neuromuscular block but did not increase speed of onset. (*Br. J. Anaesth.* 1997; **79**: 122–124).

Key words
Ions, magnesium. Pharmacology, magnesium sulphate. Neuromuscular block, rocuronium. Neuromuscular block, measurement of response.

The action of non-depolarizing neuromuscular blockers is potentiated by magnesium sulphate ($MgSO_4$)[1] and the speeds of onset of pancuronium, atracurium and vecuronium are increased by prior administration of $MgSO_4$.[2-4] The aims of this study were to determine the effects of prior administration of $MgSO_4$ 60 mg kg^{-1} i.v. on the onset and duration of rocuronium-induced neuromuscular block, and to quantify the haemodynamic effects of bolus i.v. administration of $MgSO_4$ 60 mg kg^{-1} on heart rate and arterial pressure.

Methods and results

After obtaining Institutional Review Board approval and written informed consent, we studied 30 ASA I or II patients, aged 18–65 yr, undergoing surgery requiring tracheal intubation. A prospective, randomized, double-blind study was performed.

Patients received midazolam <0.05 mg kg^{-1} i.v. as premedication if indicated clinically. After 3 min of preoxygenation, anaesthesia was induced with thiopentone 4 mg kg^{-1} and fentanyl 1.5 μg kg^{-1}, and maintained with 1–1.5% isoflurane (inspired concentration) and 66% nitrous oxide in oxygen.

The response of the first dorsal interosseous muscle of the hand to supramaximal train-of-four (TOF) stimulation of the ulnar nerve at the wrist at 10-s intervals was measured electromyographically (Relaxograph, Datex Instrumentarium, Helsinki, Finland). The forearm was wrapped with a cotton blanket to minimize cooling. After induction of anaesthesia and having established a stable twitch response (at least three successive equal responses to TOF stimulation), either $MgSO_4$ 60 mg kg^{-1} or normal saline (NaCl) was given i.v. over 1 min according to random allocation. One minute after completion of this infusion, rocuronium 0.6 mg kg^{-1} was administered via a fast flowing i.v. infusion over 5 s. The times to 90% (T1=10%) and complete (T1=0%) single twitch depression, and to initial, 10% and 25% spontaneous recovery were measured. Heart rate and arterial pressure were measured immediately before and after induction of anaesthesia, 30 s after administration of $MgSO_4$ 60 mg kg^{-1} or NaCl, and at 1-min intervals for 3 min after administration of rocuronium (Hewlett Packard Component System, Andover, MA, USA). The minimum nasopharyngeal temperature measured with a thermistor temperature probe during the study was recorded (Hewlett Packard, part no. 21075A, Andover, MA, USA).

Sample size was calculated based on the following: taking the level of statistical significance as alpha=0.05 and beta=0.2, where 1−beta=the

Correspondence to G. S.

power of the study, a difference of 20% between two groups in onset time was sought.

Effect size (onset time) = 108* s×20% = 21.6.

Standardized effect size = effect size/SD = 21.6/24* = 0.9.

*Based on previous data.[5]

Data were analysed using unpaired (pharmacodynamic variables) and paired (within-patient comparison of heart rate and arterial pressure) two-tailed Student's t tests. Significance was defined as $P<0.05$.

The two groups were similar in age, weight, sex distribution and minimum nasopharyngeal temperature. Mean onset times to T1 = 10% ($MgSO_4$ 71 (SD 20) s, NaCl 75 (23) s) and T1 = 0% ($MgSO_4$ 105 (36) s, NaCl 107 (30) s) were similar in the two groups. The time to initial recovery was longer in the $MgSO_4$ group (42.1 (16.3) min) compared with the NaCl group (25.1 (9.1) min) (fig. 1). Similarly, times to 10% and 25% single twitch recovery in the $MgSO_4$ group (49.0 (12.4) and 56.5 (13.2) min, respectively) were greater than those in the NaCl group (33.0 (11.1) and 35.6 (13.2) min, respectively) (fig. 1).

Recovery data to 25% twitch suppression were not obtained in two patients. One patient with normal renal function, who received $MgSO_4$ and who was not receiving magnesium-containing medications, had a markedly prolonged block. The first evidence of spontaneous recovery occurred 65 min after administration of rocuronium. Plasma magnesium concentration was 4.0 mmol $litre^{-1}$, 75 min after administration of $MgSO_4$ 60 mg kg^{-1}; baseline plasma magnesium concentration had not been obtained. The Relaxograph was accidentally disconnected in the second (NaCl group) patient during complete ablation of twitch response. Although arterial pressures were similar in the two groups throughout the study, heart rates in the $MgSO_4$ group were significantly greater than those in the NaCl group immediately after induction of anaesthesia (mean 83 (SD 9) and 74 (10) beat min^{-1}, respectively; $P=0.014$), after administration of $MgSO_4$ or NaCl (92 (12) and 78 (16) beat min^{-1}, respectively; $P=0.013$), and 1 min after administration of rocuronium (91 (11) and 77 (16) beat min^{-1}, respectively; $P=0.01$).

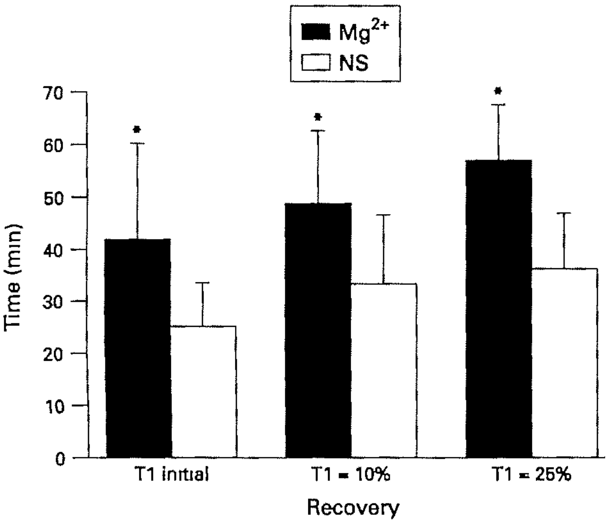

Figure 1 Times to initial recovery (T1 initial) and to T1 = 10% and T1 = 25% in the magnesium sulphate (Mg^{2+}) and normal saline (NS) groups. *$P<0.05$.

Comment

We have demonstrated that prior administration of $MgSO_4$ did not increase speed of onset, but prolonged duration of action of rocuronium-induced (0.6 mg kg^{-1}) neuromuscular block.

In the presence of high concentrations of magnesium, fewer calcium ions bind to acetylcholine containing vesicles, thus decreasing acetylcholine release from the nerve ending.[6] Postsynaptically, magnesium ions may compete with calcium ions for activation sites on the myosin ATPase necessary for excitation–contraction coupling.[7]

Previous studies of the effect of $MgSO_4$ on onset times for non-depolarizing neuromuscular blocking agents have produced conflicting results.[2–4] It appears that the shorter the "baseline" onset time, the less effect $MgSO_4$ pretreatment has on its reduction. This may be because the time of delivery of the neuromuscular blocking agent is unaffected. The remaining portion of onset time, which can be influenced by the pharmacodynamic effect of $MgSO_4$, is short, approximately 30–40 s. Similar proportionate decreases in onset time result in smaller absolute effects for fast compared with slow onset agents. For example, administration of $MgSO_4$ 60 mg kg^{-1} before pancuronium 0.1 mg kg^{-1} resulted in a fast onset time (68.3 (25.9) s). The results of this study are consistent with those of others who have shown that prior administration of $MgSO_4$ consistently prolongs neuromuscular block induced by intermediate-acting, non-depolarizing neuromuscular blocking agents.[3 4] In contrast, $MgSO_4$ 60 mg kg^{-1} did not prolong the neuromuscular blocking effects of pancuronium 0.1 mg kg^{-1}.[2] One possible explanation is that the effects of a bolus dose of $MgSO_4$ are diminished by the time that spontaneous recovery from the longer acting pancuronium begins to take place. The differences in heart rate between the $MgSO_4$ and NaCl groups immediately after induction of anaesthesia were not clinically significant. The small samples used in this study increased the likelihood of encountering such a difference randomly.

In summary, $MgSO_4$ did not increase the speed of onset, but prolonged the duration of rocuronium-induced neuromuscular block. Administration of $MgSO_4$ at this dose before rocuronium offered no clinical advantage and because an unanticipated, prolonged neuromuscular block could result, is potentially harmful.

Dystrophin deficient *mdx* muscle is not prone to MH susceptibility: an *in vitro* study

N. MADER, H. GILLY AND R. E. BITTNER

Summary

The association between malignant hyperthermia (MH) and neuromuscular disorders is controversial. An association between MH and Duchenne muscular dystrophy, a common and lethal disorder caused by deficiency of dystrophin, has been reported sporadically but is still not proved. To examine this problem, we performed halothane and caffeine *in vitro* contracture tests on skeletal muscles from dystrophin deficient *mdx* mice, an animal model for human Duchenne muscular dystrophy. As neither halothane nor caffeine triggered abnormal responses in *mdx* muscles, we conclude that dystrophin deficiency *per se* is not the primary cause of MH-like crises, as reported for patients with Duchenne muscular dystrophy. (*Br. J. Anaesth.* 1997; **79**: 125–127).

Key words
Malignant hyperthermia. Model, mouse. Complications, muscular dystrophy.

On the basis of sporadic clinical reports[1 2] an association between malignant hyperthermia (MH) has been described and several neuromuscular disorders, such as central core disease, King-Denborough syndrome, several myotonic disorders and several forms of muscular dystrophies, including Duchenne muscular dystrophy. Duchenne muscular dystrophy is an X-linked lethal muscle disorder (with an incidence of approximately 1 in 3500 male births) caused by lack of, or reduction in, dystrophin, a 427-kDa spectrin-like protein which is expressed at the inner surface of the plasma membranes of skeletal and cardiac muscle fibres.[3] In the mouse model for Duchenne muscular dystrophy (*mdx* mutant mouse), dystrophin deficiency causes only mild myopathy without clinically overt symptoms. In both conditions, human Duchenne muscular dystrophy and murine *mdx*, defective intracellular calcium homeostasis, leading to increased sarcoplasmic calcium concentrations, is considered to arise from defective muscle fibre membranes caused by deficiency of dystrophin.[1 3] Defective sarcoplasmic calcium homeostasis is also thought to be the pathophysiological basis of MH,[1 2 4 5] a hypermetabolic crisis, characterized by a rapid increase in temperature, hypercontractility and rigidity of muscles, in addition to respiratory and metabolic acidosis.[1 2] In susceptible patients, MH is triggered by inhalation anaesthetic agents (e.g. halothane) and depolarizing neuromuscular blocking agents (e.g. suxamethonium).[2 4] Although in some MH pedigrees, mutations within the ryanodine receptor gene (RYR1)[4 5] encoding a calcium regulatory membrane protein have been identified, the molecular basis is not clear for the majority of MH patients.[1] Thus defective sarcoplasmic calcium homeostasis is common to both dystrophin deficiency and RYR1 mutations. Because Duchenne muscular dystrophy is one of the most common and severe neuromuscular disorders, we carried out this study in order to determine if dystrophin deficiency and concomitant defective calcium homeostasis leads to increased MH susceptibility. For this purpose we performed *in vitro* contracture tests (IVCT) on dystrophin deficient *mdx* muscle and on normal mouse muscle.

Methods and results

Ten male C57BL/10ScSnHim*mdx* mice and 10 male normal mice (C57BL/10ScSnHim) were killed by cervical dislocation at the age of 10 weeks. Dystrophin status of *mdx* and normal mouse muscle was determined by immunohistochemistry and by Western blotting, using a dystrophin specific polyclonal antiserum raised in sheep, directed against the 60-kDa dystrophin fusion protein.[3] Immediately after cervical dislocation, both extensor digitorum longus (EDL) muscles were excised and immersed in modified Krebs–Ringer solution which was gassed continuously with 95% oxygen and 5% carbon dioxide. IVCT were performed, exposing one muscle to halothane and the contralateral muscle to caffeine. In order to accommodate for the small mouse muscles (approximate weight 0.02 g), the standard procedure of the European Malignant Hyperthermia Group[6] was modified slightly (pre-drug resting tension approximately 1 g). Muscle viability was

tested by electrical stimulation (repetition rate 0.2 Hz; pulse width 1 ms; constant current approximately 80 mA). Halothane was added to the gas-flow to achieve a final concentration of 0.11, 0.22, 0.44 and 0.66 mmol litre^{-1}, using an agent-specific vaporizer (Vapor 3.1, Dräger, Germany). Caffeine concentrations were increased cumulatively (0.5, 1, 2, 3 and 4 mmol litre^{-1}). When, after a stabilization period ($\geqslant$20 min), resting tension did not decrease by more than 0.04 mN min^{-1}, halothane and caffeine tests were started. Contractile force was evaluated from the chart records by calculating the respective drug-induced increase, that is the difference between the highest contracture which was observed within 3 min after drug administration and pre-drug force of contraction. At the end of the test, the viability of the muscles was tested using caffeine concentrations of 32 mmol litre^{-1}. As all muscles tested responded with tetanic contractures they were considered viable (tables 1, 2).

EFFECT OF HALOTHANE IVCT ON *MDX* (N=*10*) AND NORMAL MUSCLES (N=*10*)

In *mdx* muscles there were no dose-dependent increases in muscle contractures after adding halothane (table 1).

In EDL muscles from normal mice, before and after adding the drugs, transient and dose-independent increases in contractile force were recorded in three of 10 muscles exposed to halothane. However, within 1–3 min, the contractures re-stabilized at pre-drug baseline values. Apart from these transient contractures there were no increases produced by halothane.

At the end of the experiments muscle viability was tested in both groups by adding caffeine 32 mmol litre^{-1}. All muscles responded with tetanic contractures. In these tests *mdx* muscles responded with an average increase of 3.2 g, while control muscles responded with an average increase of 5.7 g (table 1).

EFFECT OF CAFFEINE IVCT ON *MDX* (N=*8*) AND NORMAL MUSCLES (N=*10*)

The caffeine test was carried out on eight of 10 *mdx* muscle specimens and no dose-dependent increases in muscle contracture were observed (table 2).

In five of 10 control muscles, transient and dose-independent increases in contractile force were recorded, as described above.

Tetanic contractures produced by addition of caffeine 32 mmol litre^{-1} at the end of the experiments

Table 1 Halothane *in vitro* contracture tests using EDL muscles from dystrophin deficient *mdx* mice (*mdx*) and from normal mice (control). All values for twitch height and contracture force are in grams. Responses to cumulative administration of halothane 0.11–0.66 mmol litre^{-1} are maximum increases above pre-drug levels. These responses are indicated as negative (neg.) or transient, dose-independent contractures, which decreased to baseline within 1–3 min; >=outside the range of recording. The response to caffeine 32 mmol litre^{-1} of control mouse No. 9 is indicated by ">1 g" because the muscle bundle tore in the presence of caffeine 32 mmol litre^{-1}

Animal No.	Pre-drug twitch height		+Halothane (0.11–0.66 mmol litre^{-1})		+Caffeine 32 mmol litre^{-1}	
	mdx	Control	*mdx*	Control	*mdx*	Control

9	<0.1	0.02	nr	neg.	nr	1.6
10	0.05	0.15	neg.	neg.	1.5	7.3

were demonstrable in both *mdx* and normal muscle specimens. The *mdx* muscles responded with an average increase of 2.1 g while the control muscles responded with an average increase of 4.2 g (table 2).

Comment

We have used the dystrophin deficient *mdx* mouse, a valid and commonly accepted animal model for Duchenne muscular dystrophy, to study if dystrophin deficiency in human Duchenne muscular dystrophy is causative for the MH-like crises which have been observed sporadically in patients with Duchenne muscular dystrophy.[1 2] Using an *in vitro* assay (i.e. IVCT) as recommended by the European MH Group[6] for MH diagnosis, we found no abnormal reactions in *mdx* muscles after exposure to either halothane or caffeine. These data strongly indicate that there is no increased MH susceptibility in dystrophin deficient *mdx* mouse muscle. Normal and dystrophic mouse muscles fulfilled the viability criteria as all muscles tested responded to the addition of caffeine 32 mmol litre^{-1} at the end of the experiments with tetanic contractures. Moreover, muscles responded to electrical stimulation by reproducible twitches in the respective IVCT experiments. For *mdx* muscles we observed relatively small twitch responses during the pre-drug period and relatively small contractile forces after adding caffeine 32 mmol litre^{-1} compared with normal mouse muscles. This phenomenon is consistent with the findings of Coulton and colleagues that *mdx* muscle shows less twitch and tetanic tension compared with normal mouse muscle.[7]

Transient, short contractures, as occurred in normal mouse muscle (three of 10 muscles in the halothane test (table 1), five of 10 muscles in the caffeine test (table 2)) can also be seen sporadically in human muscles which are finally diagnosed as MH negative (MHN) (H. Gilly, unpublished data). Although it is difficult to define a threshold for normal mouse muscle we did not observe the phenomenon of spontaneous contractures in *mdx* muscle, indicating that *mdx* muscle fulfilled the "normality criteria" with respect to the IVCT protocol which was designed for human muscle samples. In this context we cannot determine if transient contractures are specific for the normal C57BL/10 mouse strain used. As neither halothane nor caffeine induced abnormal prolonged contractures in any normal or dystrophic muscle tested, we conclude that dystrophin deficiency *per se* is not the primary cause of increased MH susceptibility.

Defective calcium homeostasis, which is common to human Duchenne muscular dystrophy and *mdx* muscle, is considered to play a crucial pathophysiological role in MH.[2 4 5] This is corroborated by the finding that missense mutations affecting the calcium regulatory domain of the ryanodine receptor (RYR1) are associated with MH in humans and in pigs.[1 4 5] However, despite defective calcium homeostasis in dystrophin deficient *mdx* muscle, we did not observe any MH related changes during halothane–caffeine IVCT. Our findings cannot exclude the possibility that in human Duchenne muscular dystrophy muscle which is more severely affected by dystrophic changes and necrotic events compared with *mdx* muscle, there might be a threshold dependent mechanism with respect to increased intracellular calcium concentrations and consequent MH susceptibility. We conclude that mechanisms other than dystrophin deficiency should be considered in the aetiology of increased MH susceptibility in human Duchenne muscular dystrophy.

Effects of ketamine and pentobarbitone on acetylcholine release from the rat frontal cortex *in vivo*

T. KIKUCHI, Y. WANG, H. SHINBORI, K. SATO AND F. OKUMURA

Summary

We have studied the effects of ketamine and pentobarbitone on acetylcholine (ACh) release from the rat frontal cortex using microdialysis. Ketamine 25, 50 and 100 mg kg^{-1} increased ACh release from the frontal cortex to 286%, 253% and 381% of basal release, respectively. In contrast, pentobarbitone 10, 20 and 40 mg kg^{-1} caused 73%, 78% and 96% inhibition of basal levels, respectively. The results suggest that ketamine and pentobarbitone have opposite effects on ACh release from the rat frontal cortex, as seen previously in the rat hippocampus. (*Br. J. Anaesth.* 1997; **79**: 128–130).

Key words

Nerve, neurotransmitters. Anaesthetics i.v., ketamine. Hypnotics barbiturate, pentobarbitone. Brain, cerebral cortex. Rat.

Cholinergic neurones, which are distributed widely in the brain, have been implicated in a variety of functions, such as memory, learning and motor function. However, the effects of various anaesthetics on cholinergic neurones are not well understood at the molecular level.

Recently, brain microdialysis techniques combined with HPLC-ECD have been well established for measurement of acetylcholine (ACh). In previous studies[1] using this microdialysis technique, we have already shown differential effects of ketamine and pentobarbitone on ACh release from rat hippocampus and striatum, and also demonstrated that the stimulating effect of ketamine might be involved in dopamine D_1 receptor mechanisms.

Determination of ACh release in brain regions such as the cortex, hippocampus, striatum or medial pontine reticular formation is relevant for the study of anaesthetic mechanisms as ACh is thought to be one of the important neurotransmitters involved in the action of anaesthetics.[2 3] The purpose of this study was to investigate the effects of ketamine and pentobarbitone on ACh release from the rat frontal cortex.

Methods and results

Microdialysis experiments were performed on 30 male adult Sprague–Dawley rats, weighing approximately 300 g, during free movement, at least 2 days after implantation of a microdialysis probe.[1] The study was approved by the Animal Welfare Committee of Yokohama City University School of Medicine. The animals, anaesthetized with sodium pentobarbitone 40 mg kg^{-1} i.p. were placed in a stereotaxic frame (Model SR-6, Narisige Scient Instrument LAB., Japan) and the intracerebral guide cannula (CMA 10, Carnegie Medicine, Sweden) was implanted stereotaxically into the right frontal cortex (coordinates taken from bregma with skull flat: A=3.3 mm, L=2.8 mm, V=0.5 mm from the atlas of Paxinos and Watson) and fixed in place using dental cement. The probes (CMA 11, Carnegie Medicine, Sweden) (2-mm long dialysis membrane, od 0.24 mm, molecular weight cut-off=20 000 Da) were perfused with Ringer's solution containing eserine sulphate 10 μmol $litre^{-1}$ (Wako Pure Chemical Industries Ltd., Japan), an inhibitor of choline esterase, at a rate of 2.0 μl min^{-1} using a microperfusion pump (Model CMA 102, Carnegie Medicine, Sweden). After pre-perfusion with Ringer's solution for 120 min, each sample was collected for 20 min in a cooled polyethylene tube containing 10 μl of ethylhomocholine 1 μmol $litre^{-1}$, an internal standard for high performance liquid chromatography (HPLC) determination. The test drugs were ketamine 25, 50 and 100 mg kg^{-1} i.p. (Sankyo Ltd., Japan) and pentobarbitone 10, 20 and 40 mg kg^{-1} i.p. (Abbott Laboratories, USA). After collecting three basal samples, the test drugs were administered i.p. ACh was assayed by a method described previously.[1] The limit of sensitivity was 100 fmol (100 fmol/50 μl injection). At the end of the experiments, the animals were killed with an overdose of diethyl ether, and the position of the probe in the brain was confirmed by visual examination.

Mean ACh recovery through the probes at a rate of 2 μl min^{-1} was 11.1 (SEM 0.7) % (n=5). ACh release was expressed as a percentage of basal values. Basal release was obtained from the mean of three initial collections before administration of the test drugs. The significance of differences between mean

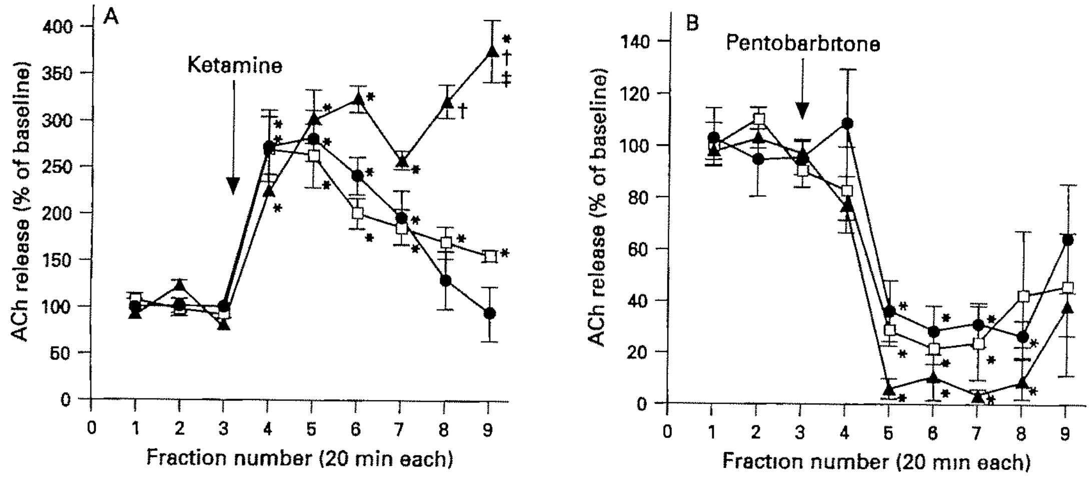

Figure 1 A: Effects of ketamine 25 mg kg^{-1} (●, $n=5$), 50 mg kg^{-1} (□, $n=5$) and 100 mg kg^{-1} (▲, $n=5$) i.p. on acetylcholine (ACh) release. *$P<0.05$ compared with pre-drug values; †$P<0.05$ compared with ketamine 25 mg kg^{-1}; ‡$P<0.05$ compared with ketamine 50 mg kg^{-1} according to ANOVA with *post hoc* Scheffé's *F* test. B: Effects of pentobarbitone 10 mg kg^{-1} (●, $n=5$), 20 mg kg^{-1} (□, $n=5$) and 40 mg kg^{-1} (▲, $n=5$) i.p. on acetylcholine (ACh) release. *$P<0.05$ compared with pre-drug values according to ANOVA with *post hoc* Scheffé's *F* test for multiple comparisons. Data are group mean (SEM)

values was determined by ANOVA with repeated measures, followed by Scheffé's *F* test for multiple comparisons. $P<0.05$ was considered statistically significant.

In this experiment, ketamine 25, 50 and 100 mg kg^{-1} i.p. and pentobarbitone 10, 20 and 40 mg kg^{-1} i.p. produced a sleeping state in all rats within 10 min which lasted throughout the experiment.

ACh release was stable over 120 min after the beginning of perfusion. Baseline ACh concentration from the frontal cortex in 20-min samples was 0.90 (SEM 0.07) pmol per sample ($n=30$).

Figure 1A shows the effects of ketamine on ACh release from the frontal cortex. Ketamine 25, 50 and 100 mg kg^{-1} i.p. increased ACh release from the frontal cortex. The maximum increases in ACh release produced by ketamine 25, 50 and 100 mg kg^{-1} i.p. were 286%, 253% and 381% of basal levels, respectively. The mean increase in ACh release reached a maximum value within 40 min after administration of ketamine 25 and 50 mg kg^{-1}; subsequently there was a gradual decrease. However, ACh produced by ketamine 100 mg kg^{-1} continued to increase over the entire experimental period representing a biphasic pattern.

In contrast, as shown in figure 1B, pentobarbitone 10, 20 and 40 mg kg^{-1} i.p. decreased ACh release from the frontal cortex. The maximal effects of pentobarbitone 10, 20 and 40 mg kg^{-1} i.p. were 73%, 78% and 96% inhibition of basal levels, respectively.

Comment

The frontal cortex comprises the motor area and the association area, the so called *prefrontal cortex*, that is concerned with concentration, attention, initiative and spontaneity. Both the frontal cortex and hippocampus receive cholinergic projections mainly from the anterior and posterior regions of the cholinergic basal nuclear complex, respectively.[4] Behavioural and pharmacological evidence suggests that regulation of cortical and hippocampal cholinergic activity is often similar. The increase in ACh release in the cortex reflects the desynchronized electroencephalogram (EEG) during wakefulness and REM sleep.[5]

Pentobarbitone decreased ACh release from the rat frontal cortex, as seen in the rat striatum and hippocampus,[1] which strongly supports the concept that pentobarbitone has a "depressant" anaesthetic effect. It is generally believed that various barbitones such as pentobarbitone produce marked and persistent enhancement of the function of the gamma-aminobutyric acid (GABA)$_A$ coupled chloride channel and reduce glutamate-induced depolarization. Furthermore, there is abundant evidence that barbitones depress cortical EEG activity, and cholinergic neural activity in the cortex correlates positively with cortical EEG activity,[3] which is in agreement with our findings.

Ketamine increased ACh release from the rat frontal cortex as seen in the rat hippocampus.[1] However, the increase in ACh produced by ketamine 100 mg kg^{-1} showed a biphasic pattern, which was not seen in the hippocampus in our previous study. Although reasons for a biphasic pattern are unknown, a high dose of ketamine may affect ACh release from the frontal cortex via mechanisms different from those after a low dose of ketamine.

Ketamine is known to produce psychostimulant defects such as hyperactivity and memory impairment. It is generally accepted that ketamine is a non-competitive antagonist of NMDA receptors, and there are reports which suggest that ketamine acts at an NMDA recognition site, indicating a role for NMDA receptors in concept learning. NMDA receptors are present in high density in the rat cortex and hippocampus.[6] Hasegawa and colleagues showed that MK-801, another non-competitive antagonist at the NMDA receptor but not an anaesthetic agent, increases ACh release in the rat parietal cortex and that the facilitatory effects of MK-801 on cortical ACh release are blocked by NMDA.[7] This may indicate that the facilitatory effect of ketamine on ACh release from the rat cortex appears to be involved in the antagonism of NMDA receptors, as shown with our previous data for rat hippocampal ACh release.[1]

Our results demonstrated that both ketamine and pentobarbitone produced loss of consciousness, but opposite effects on ACh release from the cortex. This suggests that ACh release in the frontal cortex is concerned with psychomimetic effects other than consciousness. These opposing effects of ketamine and pentobarbitone on cortical ACh release lead us to speculate that the unfavourable psychomimetic actions of ketamine such as bad dreams may be suppressed by simultaneously administered barbitones. Furthermore, several classes of NMDA antagonists, including ketamine, are known to produce morphological damage in neurones in the cerebral cortex and this may be prevented by barbitones, benzodiazepines, or both.[8]

Although the underlying biochemical mechanisms remain to be determined, these opposite effects of ketamine and pentobarbitone on ACh release from the cortex may partly suggest a mechanism underlying the different effects of "dissociative" and "depressant" anaesthetics.

The transient hyperaemic response (THR) of blood flow velocity in the middle cerebral artery after a brief compression of the common carotid artery has been validated as an indicator of cerebral autoregulation.[1] A theoretical model for the quantitative assessment of cerebral autoregulation using the THR has been described by our department.[2] The aim of this study was to determine the effects of breathing 100% oxygen or 50% nitrous oxide in oxygen on cerebral autoregulation.

Eight healthy volunteers were studied in the supine position. Continuous recordings of both cerebral blood flow velocity in the left middle cerebral artery, using transcranial Doppler ultrasonography, and end-tidal carbon dioxide partial pressure at the mouth were established. Each volunteer was subjected to two compressions of the left common carotid artery of 10 s duration while breathing air for baseline measurements. Subsequent measurements were made while breathing 100% oxygen or 50% nitrous oxide in oxygen at fresh gas flow rates of 9–12 litre min^{-1} via a Mapleson A breathing system. Before each compression end-tidal carbon dioxide partial pressure, mean arterial pressure (MAP) and percentages of expired oxygen and nitrous oxide were recorded. Time-averaged mean velocities of the middle cerebral artery pulse waves were analysed as follows: the pulse wave immediately before compression (F1), then immediately after compression (F2) and the first pulse wave after release (F3). Strength of autoregulation (SA) was calculated from the formula (F3/F1)×(P2 /MAP). P2 is the estimated value of the reduced MAP in the middle cerebral artery resulting from carotid artery compression. The value for P2 used in calculating strength of autoregulation is the greater of either that derived from MAP×F2/F1 or 60 mm Hg (assumed lower limit of autoregulation).

Two volunteers could not tolerate 50% nitrous oxide and were excluded from the study. MAP and end-tidal carbon dioxide measurements did not change significantly in any of the subjects.

Breathing 50% nitrous oxide significantly reduced SA compared with air or 100% oxygen ($P<0.01$, paired *t* test). Breathing 100% oxygen resulted in a slight increase in SA compared with air but this was not statistically significant and is not likely to be clinically significant.

In conclusion, the strength of autoregulation was impaired significantly while breathing 50% nitrous oxide.

Table 1 Effect of 100% oxygen and 50% nitrous oxide in oxygen on SA

	Air (n=6)	100% Oxygen oxide (n=6)	50% Nitrous
SA (SD)	0.98 (0.09)	1.09 (0.17)	0.77 (0.11)

Key words
Anaesthetic gases, nitrous oxide. Brain, autoregulation.

Comparison between reverse Fick and indirect calorimeter measurements of oxygen consumption in patients with fulminant hepatic failure

T. S. Walsh *, P. Hopton* and A. Lee
Department of Anaesthetics and Scottish Liver Transplant Unit, Royal Infirmary, Edinburgh

The reverse Fick method of calculating oxygen consumption ($\dot{V}O_2$) requires multiple clinical measurements, each of which has an associated measurement error. Previous studies in post-cardiac surgery[1] and general intensive care[2] patients have compared this method with indirect calorimeter measurements which are based on analysis of respiratory gases. In these studies the agreement between the methods was poor. In patients with fulminant hepatic failure (FHF) a large cardiac output and small arteriovenous oxygen content difference (AV difference) are typical. This is likely to result in large measurement errors with the reverse Fick method. In this study we compared simultaneous measurements of $\dot{V}O_2$ made with the two techniques in patients with FHF under typical clinical conditions.

Seventeen patients admitted to the intensive care unit with FHF were studied. All patients were sedated, paralysed and their lungs ventilated because of grade III/IV encephalopathy and were resuscitated with fluids and normal adrenaline infusions, as indicated clinically before starting the study. A Deltatrac metabolic monitor (Datex) was used to determine $\dot{V}O_2$ by the gas exchange method. For reverse Fick calculations, cardiac output was measured with the Vigilance system (Baxter). Blood samples from arterial and pulmonary artery catheters were analysed within 5 min of collection with an IL 482 co-oximeter and IL BGE 1400 series analyser. $\dot{V}O_2$ was calculated using the standard formula.

Eleven patients received a standard infusion regime of *N*-acetylcysteine at the start of the study which increases cardiac output in patients with FHF.[3] Six patients received fluids only. Over a 5-h period six pairs of measurements were made in each patient at 0, 30, 60, 120, 180, and 300 min. At each time a 10-min average of cardiac output and gas exchange $\dot{V}O_2$ was recorded.

The mean cardiac index was 5.7 (range 3.4–9.5) litre min^{-1} m^{-2}, Sa_{O_2} 99% (95.4–100%), $S\bar{v}O_2$ 86.3% (75.1–90.5%), AV difference (1.0-2.8) 1.7 ml dl^{-1}. Ninety-eight pairs of measurements were obtained. These were compared with the Bland and Altman method which indicated a negative bias of reverse Fick calculations relative to gas exchange measurements of −41 ml min^{-1} m^{-2} (95% CI −35 to −47). For pooled data the limits of agreement were -101 to $+19$ ml min^{-1} m^{-2}. The mean bias in individual patients ranged from -73 to $+13$ ml min^{-1} m^{-2} and was not related to the mean $\dot{V}O_2$ ($r=0.11$).

The reproducibility of each method was compared by calculating the within-patient standard deviation ($S\omega$) of $\dot{V}O_2$ data using analysis of variance. The ratio of the values of $S\omega$ is then an index of the relative reproducibility of the techniques. For reverse Fick data $S\omega=15$ ml min^{-1} m^{-2}, for gas exchange data $S\omega=7$ ml min^{-1} m^{-2}, ratio 2.2.

Our data indicated that in patients with FHF the agreement between the reverse Fick and gas exchange methods of determining $\dot{V}O_2$ was very poor. The limits of agreement which we calculated were wider than those reported in previous studies in other patient groups. Reverse Fick calculations underestimated gas exchange measurements by an amount which varied widely between patients. The reproducibility of reverse Fick calculations was worse than gas exchange measurements probably because of the small AV difference which typifies these patients. Although neither method was a gold standard our data suggest that the disagreement between the methods is largely attributable to measurement errors in reverse Fick calculations.

Key words

Desflurane *vs* isoflurane in liver transplantation: a comparison of outcomes

H. A. O'Beirne, Y. Young, J. Thornton* and M. C. Bellamy
Intensive Care Unit, St James's University Hospital, Leeds

During major surgery, splanchnic blood flow is better preserved with desflurane anaesthesia than with isoflurane anaesthesia.[1] We have therefore studied their effects on outcome after liver transplantation in humans.

In a prospective randomized controlled trial, we studied 40 patients undergoing elective liver transplantation. Twenty received desflurane and 20 isoflurane as part of a standard anaesthetic according to our usual technique.[2] Anaesthesia was induced by a high dose opioid-benzodiazepine sequence. Neuromuscular block was produced with atracurium. Patients' lungs were ventilated to normocapnia using oxygen-enriched air, supplemented with 1 MAC of volatile agent. All patients received dopamine 3 μg kg^{-1} min^{-1}. Liver laser Doppler flowmetry was measured after graft re-perfusion, and again immediately before abdominal closure. We measured alanine aminotransferase (ALT), bilirubin, prothrombin time (PT) at 3 and 7 days after surgery. Results are median (range) and were compared using Mann-Whitney *U* test.

Groups were comparable in age, diagnosis, intraoperative blood loss and Child-Pugh score. In the desflurane group, liver blood flow was 67 perfusion units (range 17–219) at re-perfusion, compared with 66 (7–293) in the isoflurane group. At abdominal closure, these values were 70 (13–342), compared with 70 (25–112) perfusion units. There were six serious adverse events in the isoflurane group, but none in the desflurane group ($P=0.02$, Fisher's exact test). Hospital stay for isoflurane patients was 21 (10–47) days compared with 20 (12–57) days in the desflurane group (n.s.).

Table 2 Effect of desflurane and isoflurane on liver function

	Desflurane	Isoflurane	*P*
PT (day 3)	17 (11–27)	17 (13–37)	n.s.
PT (day 7)	14 (12–27)	15 (12–22)	n.s.
ALT (day 3)	239 (52–1787)	534 (34–3170)	0.09
ALT (day 7)	91 (37–294)	176 (49–925)	0.05
BILI (day 3)	63 (16–164)	84 (19–436)	0.07
BILI (day 7)	45 (16–148)	77 (20–318)	0.04

No direct effects of dopexamine on the isolated perfused rat kidney

M. Leuwer, P. Thum*, K. Kirchhoff*, A. Bornscheuer*, W. Seitz*, S. Piepenbrock*, E. Kirchner*
Department of Anaesthesiology, Hannover Medical School and Institute for Peptide Research, Hannover, Germany

Dopexamine, a synthetic catecholamine is thought to increase mesenteric[1] and renal [2] blood flow. It is a specific agonist at type 1 and 2 dopamine receptors and α-adrenergic receptors and has been reported to prevent renal impairment in patients undergoing orthotopic liver transplantation.[3] However, to date there are few reports showing a direct influence of dopexamine on the kidney.[4] Therefore, we investigated the effects of dopexamine in comparison with those of dopamine on renal blood flow (RBF), urine production (UP), glomerular filtration rate (GFR), sodium excretion (U_SV) and fractional sodium reabsorption (FR_s) in an isolated perfused kidney model.[5]

The study was conducted after approval of the local animal protection committee. The right kidney was taken from 40 male Wistar rats. After catheterization of the renal artery and ureter, respectively, the organ was introduced into a closed system and perfused by a substrate-enriched Krebs-Henseleit buffer solution with 5% bovine albumin. Perfusion pressure was 100 mm Hg. After an equilibration period of 20 min and two control periods of 10 min each, dopamine 2.0 mg kg min^{-1} or dopexamine 1.0, 2.5 or 4.0 mg kg min^{-1} were added at random. RBF, UP, GFR, U_sV and FR_s were determined 10, 20, 30 and 40 min after the start of infusion. Urine was collected every 10 min for an 80-min period. Data are presented as mean values (SD). Student's *t* test was used for statistical analysis. $P<0.05$ was considered significant.

Dopamine significantly increased urine production from 77.87 (7.5) to 117.2 (9.7) μl/min x g and absolute sodium excretion from 0.6 (0.1) to 1.2 (0.1) μmol/min x g. Fractional sodium reabsorption significantly decreased from 95.3 (0.4) to 90.7 (0.7) %. Renal blood flow and glomerular filtration rate did not change. In contrast with dopamine none of the dopexamine concentrations tested revealed any significant effects on these parameters.

Dopexamine had no direct effects on the function of the isolated perfused rat kidney.

Naloxone inhibits gastric emptying but not gastrointestinal transit in the rat

T. Asai, W. W. Mapleson and I. Power
Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff, and Department of Anaesthesia and Pain Management, University of Sydney, RNSH, St Leonards, Australia

Naloxone is generally considered to be a pure antagonist.[1] However, it may produce a hyperalgesic or antinociceptive effect in several species; the effect does not increase systematically with dose, but shows a maximum effect at 1– 3 mg kg^{-1} in rodents when given peripherally.[2 3] We observed that naloxone inhibited gastric emptying in the rat.[4] Therefore, we formally studied the effect of naloxone on gastric emptying and gastrointestinal transit in the rat.

Six to eight Wistar rats (200–250 g) were used for each group. Either saline or naloxone (0.01 – 10 mg kg^{-1}) was injected i.p. at 0 min. At 30 min, radiolabelled saline 1 ml was infused into the stomach. At 1 h, the animal was killed, the gastrointestinal tract was removed and the small intestine was divided into 10 equal segments. Radioactivity in the stomach and each segment of the intestine was counted, and gastric emptying and gastrointestinal transit were calculated. Gastrointestinal transit was assessed using the "geometric centre" ($\Sigma(CiSi)/\Sigma Ci$ where Ci=count in segment Si).[4] The Mann-Whitney *U* test was used to compare gastric emptying or gastrointestinal transit between saline and pooled data for all doses of naloxone. We also calculated 95% confidence limits (CL) for the difference between saline and naloxone in terms of median values for gastric emptying or gastrointestinal transit. A parabola was fitted to the variation of effect with log dose to see if there was any evidence of a peak effect.

Naloxone significantly inhibited gastric emptying ($P<0.001$), but not gastrointestinal transit ($P>0.05$) (table 3). Only gastric emptying showed a significant peak ($P<0.05$) in the dose-response curve – at 0.7 mg kg^{-1}.

Table 3 Effect of naloxone on % gastric emptying (GE%) and gastrointestinal transit (GIT) (median (range) and 95%CL [of median] for difference from 0 dose)

Doses (mg kg^{-1})	GE (%)	95% CL of difference	GIT	95% CL of difference
0	84.3 (82.7, 92.7)	—	5.2 (3.9, 6.2)	—
0.1	66.1 (56.3, 87.0)	[−2.1, 27.3]	4.7 (3.8, 5.5)	[20.7, 1.3]
0.3	75.7 (54.8, 83.5)	[5.4, 27.9]	4.5 (3.8, 5.1)	[0.0, 1.7]
1	59.8 (53.3, 68.9)	[16.0, 31.6]	4.8 (3.3, 5.6)	[−0.5, 1.6]
3	72.4 (55.9, 87.4)	[5.1, 26.8]	4.5 (3.3, 5.2)	[−0.5, 1.8]
10	76,8 (68.5, 82.7)	[2.2, 15.3]	4.6 (3.6, 5.5)	[−0.4, 1.6]

Naloxone significantly inhibited gastric emptying with a peak effect at approximately 1 mg kg^{-1}, but did not significantly inhibit gastrointestinal transit in the rat.

Key words
Gastrointestinal tract, emptying. Pharmacology, naloxone. Antagonists opioid, naloxone.

Interactive effects of morphine and dexmedetomidine on gastrointestinal transit and gastric emptying in the rat

T. Asai, W. W. Mapleson and I. Power
Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff, and Department of Anaesthesia and Pain Management, University of Sydney, RNSH, St Leonards, Australia

Dexmedetomidine markedly inhibits intestinal transit, but only weakly inhibits gastric emptying; morphine strongly inhibits both.[1] Therefore, we studied the effect of a combination of these two agonists on gastrointestinal transit and gastric emptying in the rat.

Five to eight male Wistar rats (200–250 g) were used for each group. A different combination of the drugs was administered to each group at 0 min; radiolabelled saline 1 ml was infused into the stomach at 30 min, and at 1 h the animal was killed, the gastrointestinal tract was removed and (where relevant) the small intestine was divided into 10 equal segments. Radioactivity in the stomach and in each segment of the intestine was counted; gastric emptying and gastrointestinal transit were calculated.[1] To study the effect on gastrointestinal transit, the two drugs were injected i.p. in a fixed ratio (30: 1) — that of their ED_{50} values [1] — in six doses, each to a different group of rats. These doses (0.062–1.075 mg kg^{-1}) bracketed the ED_{50} predictable on the basis of additivity. The ED_{50} of the mixture, its variance and 95% confidence limits (CL) were determined,[1] and compared with those predicted on the basis of additivity.[2] To study the effect on gastric emptying, another six groups of rats each received a different mixture i.p.: (1) saline and saline; (2) dexmedetomidine 0.01 mg kg^{-1} and saline; (3) morphine 0.22 mg kg^{-1} (ED_{25}) and saline; (4) morphine 0.22 mg kg^{-1} and dexmedetomidine 0.01 mg kg^{-1}; (5) morphine 2.8 mg kg^{-1} (ED_{50}) and saline; (6) morphine 2.8 mg kg^{-1} and dexmedetomidine 0.01 mg kg^{-1}. The Mann-Whitney *U* test was used for comparison of mixtures.

There was a supra-additive interaction between morphine and dexmedetomidine for the inhibitory effect on gastrointestinal transit (fig. 1). Dexmedetomidine 0.01 mg kg^{-1} inhibited gastric emptying ($P<0.01$; CL for difference from saline: (−16%, −5%)), but did not significantly alter the inhibitory effect of morphine on gastric emptying ($P=0.7$ for both doses).

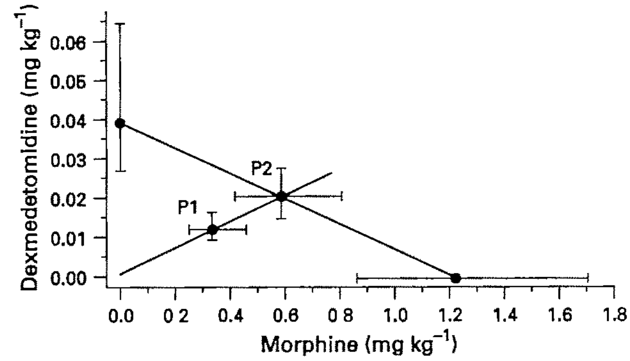

Figure 1 Effect of i.p. morphine and dexmedetomidine on gastrointestinal transit. The observed ED_{50} (0.351 mg kg^{-1}) for the 30:1 mixture (with CL) (point P1) is below the line connecting the ED_{50} values for the two drugs, showing a supra-additive effect; the point P2 is the ED_{50} (0.625 mg kg^{-1}) for the mixture on the basis of additivity; difference in ED_{50} values=0.275, SEM difference=0.114, t =2.4, P=0.02.

In the rat, dexmedetomidine markedly enhanced the inhibitory effect of morphine on gastrointestinal transit, but did not significantly alter the effect of morphine on gastric emptying.

Comparison of rocuronium and suxamethonium for use during rapid sequence induction of anaesthesia

K. C. McCourt*, L. Salmela*, M. Carroll*, C. M. Kerr*, R. K. .Mirakhur and K. T. Olkkola*
Department of Anaesthetics, The Queen's University of Belfast, Belfast and Department of Anaesthesia, University of Helsinki, Helsinki, Finland

Rocuronium, among the currently available non-depolarizing neuromuscular blocking agents, has the most rapid onset of action, approaching that of suxamethonium when used in doses of 0.6–0.9 mg kg^{-1} and provides intubating conditions comparable with those of suxamethonium at 60 s.[1,2] In this randomized study we compared intubating conditions after suxamethonium or rocuronium during rapid sequence induction.

Three hundred and forty-eight, ASA grade I-IV, patients were enrolled in this two centre study with their written informed consent. The technique of tracheal induction involved preoxygenation for 3 min, administration of fentanyl 1-2 μg kg^{-1} and thiopentone 3-5 mg kg^{-1}, application of cricoid pressure and intubation 60 s after administration of rocuronium 0.6 or 1.0 mg kg^{-1} or suxamethonium 1.0 mg kg^{-1}. Intubating conditions were assessed by an observer blinded to the blocker administered and graded as excellent, good or poor based on standard criteria, the first two grades being considered clinically acceptable.[3] Intubating conditions were analysed statistically using the Mantel-Haenszel chi-square test.

Intubating conditions between the two doses of rocuronium were compared after 63 patients each had been given rocuronium 0.6 and 1.0 mg kg^{-1}, respectively. As the conditions were qualitatively better with the higher dose, further enrolment was made only in the rocuronium 1.0 mg kg^{-1} and suxamethonium groups. In all 318 patients were considered evaluable (61 and 130 for rocuronium 0.6 and 1.0 mg kg^{-1} respectively and 127 for suxamethonium).

The frequency of clinically acceptable intubating conditions was not significantly different between the groups receiving suxamethonium 1.0 mg kg^{-1} and rocuronium 1.0 mg kg^{-1} (P=0.82: table 4). However, excellent conditions were observed more frequently with suxamethonium (P=0.02). We conclude that rocuronium 1.0 mg kg^{-1} can be used during rapid sequence induction of anaesthesia as an alternative to suxamethonium or when the latter is contraindicated. A slightly later intubation time may have to be chosen for attaining uniformly excellent intubating conditions with rocuronium. Careful evaluation of the airway is also important when using rocuronium in view of its longer duration of action.

Table 4 Intubating conditions

Intubating Conditions	Rocuronium 0.6 mg kg^{-1}	Rocuronium 1.0 mg kg^{-1}	Suxamethonium 1.0 mg kg^{-1}
Excellent	17 (28%)	85 (65%)	101 (80%)
Good	29 (47%)	40 (31%)	22 (17%)
Poor	15 (25%)	5 (4%)	4 (3%)

Genetic analysis reveals single recombinants in malignant hyperthermia

J. L. Curran*, W. J. Hall*, P. J. Halsall*, P. M. Hopkins, D. E. Iles*, A. F. Markham*, R. L. Robinson*, S. P. West* and F. R. Ellis
Malignant Hyperthermia Investigation Unit, St James's University Hospital, Leeds

Malignant hyperthermia (MH) is an autosomal dominant genetic disorder manifesting under general anaesthesia. In 1990 a new paradigm in the genetics of MH was established with reports of a locus on chromosome 19q13.2, RYR1.[1,2] However in those studies several of the families described would not be classified as MH if the "gold standard" for diagnosis, the *in vitro* contracture test (IVCT) following the European MH group protocol had been adhered to. Genetic heterogeneity in MH is well established with loci in single families linked to chromosomes 3 and 7 [3,4] and only approximately 60% of families appear to be linked to RYR1. In addition we have recently found linkage to the myotonic dystrophy region (DM) on 19q13.3 in several families (unpublished results), including families in whom linkage to RYR1 has been excluded. We present the results of genetic linkage studies carried out on the largest ever reported series of families to have been screened by the European MH group IVCT protocol. A collection of genetic markers was chosen to see if it would be feasible to move towards DNA based diagnosis.

We have examined 33 large well-characterized MH families with hypervariable microsatellite markers around two of the candidate MH loci (RYR1 and DM). Primers for the markers D19S224, 208, 421, 422, 219, 112 and the CTG repeat in DM were synthesized with a fluorescent tag on the 5′ primer. Polymerase chain reactions (PCR) were performed under standard conditions, and the resultant products analysed on an ABI Genescanner. Results were analysed using Genotyper 1.1 and Cyrillic 2.1 software, followed by statistical analysis with LINKAGE 5.4. Essentially, this involves characterizing the association between inheritance of the disease phenotype (MH susceptibility) and different alleles of the various markers. When a consistent association between particular alleles of markers in the region of a chromosomal locus and the presence of the disease is found, the disease is said to segregate with that locus. If an individual member of a family does not fit the pattern they are termed a recombinant individual. The LINKAGE program provides an objective estimate of likelihood that the disease is truly associated with the locus.

Of the 35 families, 18 clearly segregated with either RYR1 or DM (or with both). Five families failed to show segregation with either of these loci, and are currently being screened with markers for those loci reported previously in single families.[3,4] The remaining 12 families give the most cause for concern, as one member only in each family was found to be recombinant. It is these families in particular that would currently make a move towards DNA based diagnosis of MH extremely unwise.

Effect of assuming a fixed $(Ca_{O_2}-C\bar{v}_{O_2})$ on shunt calculations

M. Nirmalan*, T. Willard, A. Khan* and P. Nightingale
Intensive Care Unit, South Manchester University Hospitals, Manchester

Measured shunt is considered the most accurate index for quantifying defects in oxygenation. When shunt cannot be measured, the concept of "virtual shunt" using iso-shunt diagrams has been used as a possible surrogate. Oxygen content difference between arterial and mixed venous blood, $(Ca_{O_2}-C\bar{v}_{O_2})$ is assumed to be 5 ml dl^{-1} in the construction of these iso-shunt diagrams. In critically ill patients however, an extraction of 3.5 ml dl^{-1} of oxygen may be a more appropriate value. It has been shown that virtual shunts predicted using $(Ca_{O_2}-C\bar{v}_{O_2})=3.5$ ml dl^{-1} were similar to measured shunts.[1] We have therefore tested the hypothesis that modified iso-shunt curves using $(Ca_{O_2}-C\bar{v}_{O_2})=3.5$ ml.dl^{-1} are likely to be more accurate than the original curves for predicting shunts in critically ill patients.

A total of 211 paired readings of measured and predicted shunt fractions (using two sets of iso-shunt curves) were obtained during a 48-h period from 44 patients. All patients had an indwelling pulmonary artery catheter and arterial cannula, and blood-gas measurements were carried out when indicated clinically. The Bland-Altman statistical test was used to assess the agreement between measured and predicted shunt fractions. Figure 2 shows the comparison between measured shunt and predicted shunt using the new curves.

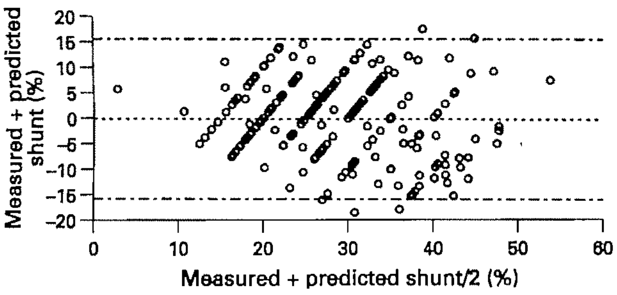

Figure 2 Agreement between measured and predicted shunt using 3.5 ml dl^{-1} for $(Ca_{O_2}-C\bar{v}_{O_2})$

The curves using $(Ca_{O_2}-C\bar{v}_{O_2})=3.5$ ml dl^{-1} over estimated the shunt with a bias of −0.23, whereas the curves using $(Ca_{O_2}-C\bar{v}_{O_2})=5$ ml dl^{-1} under estimated the shunt with a bias of +6.5 (with 95% confidence intervals for bias of 1.1% and limits of agreement of 16%, for both curves). We found a wide range of $(Ca_{O_2}-C\bar{v}_{O_2})$ values (mean 3.62 ml dl^{-1}, range 1.3–7.4 ml dl^{-1}) and wide within-patient variability (mean 1.48 ml dl^{-1}, range 0.6–4.3 ml dl^{-1}). As this lead to wide limits of agreement (16%), these charts cannot be used to accurately quantify defects in oxygenation in the lungs. Our results question the clinical validity of methods that assume a fixed value for $(Ca_{O_2}-C\bar{v}_{O_2})$ in shunt calculations.

Dose-dependent effects of halothane on contraction of rat ventricular myocytes

L. A. Davies*, S. M. Harrison*, M. R. Boyett* and P. M. Hopkins
Department of Physiology and the Academic Unit of Anaesthesia, University of Leeds, Leeds

Volatile general anaesthetics have been shown to cause depression of contraction of cardiac muscle (for example, Housmans and Murat [1]). We have investigated the negative inotropic effect of a range of halothane concentrations on the contractility of rat ventricular myocytes. Freshly isolated myocytes were superfused with a physiological salt solution at 30°C and contractions elicited by field stimulation at 1 Hz. Contractions were recorded before, during and after 1-min exposure to a solution containing halothane at concentrations in the range 0.01 to 10 mmol litre^{-1}. Halothane was added from 0.5 or 2 mol litre^{-1} stock solutions in DMSO. Figure 3A shows that during the first few seconds after exposure to halothane there was marked potentiation of contractions, followed by a pronounced and maintained negative inotropic effect. When halothane was washed off there was further transient depression of contractions which then recovered to control values. The initial potentiation of contraction was more marked with higher halothane concentrations. Figure 3B illustrates the dose-dependency of the maintained decrease in contraction (expressed as a percentage of control) induced by halothane. These data were fitted with a Hill curve with a K_d of 0.5 mmol litre^{-1} and a Hill coefficient of 1.2. These results show a dose-dependent inhibitory action of halothane on cardiac contractility at a range of halothane concentrations encompassing those seen clinically (0.05–0.69 mmol litre^{-1})[2]

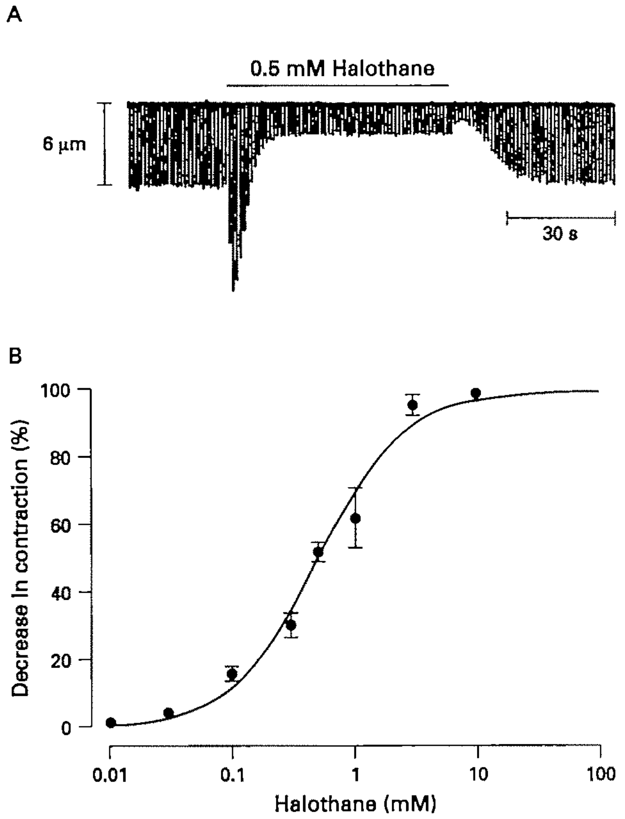

Figure 3 (A) Effect of 0.5 mmol litre^{-1} halothane (applied during the period shown by the bar) on contraction (shortening of the cell during each contraction shown) of a rat ventricular myocyte. (B) Dose-dependence of the negative inotropic effect of halothane. Means (SEMS) ($n=6$–40).

Ultrasonographic measurement of gastric emptying in volunteers: assessment of technique and effect of low-dose dopamine

D. R. Goldhill, S. A. White*, N. O. Owen* and W. Hately*
The Anaesthetics Unit and Radiology Department, The Royal London Hospital, London

The objectives of this pilot study were to determine the variability in gastric emptying measured ultrasonographically and the effect of low-dose dopamine. Dopamine at 8 μg kg min^{-1} decreased gastric emptying in volunteers [1] and dopamine 2–4 μg kg min^{-1} appeared to decrease gastric emptying in ICU patients.[2]

The cross-sectional area of the gastric antrum was measured ultrasonographically in the sitting position in two sagittal planes, at the level of the aorta and the inferior vena cava (IVC) [3] in six healthy, starved volunteers. Antral area was calculated from the maximal anteroposterior (AP) and longitudinal diameters (L) by the formula AP=L π/4. To estimate gastric emptying a baseline measurement was made and subjects ingested 500 ml of sterile water at a known temperature. Repeated measurements of antral area were made at intervals of 2.5 min for 25 min (control). Using a double-blind, randomized design subjects then received an infusion of saline or dopamine 3 μg kg min^{-1}. After 2 h of infusion measurements were repeated. Each subject received both saline and dopamine with an interval of at least 1 week between studies.

At each time the average of the antral area at the aorta and IVC was calculated. The area increased after drinking water then decreased over 25 min. The decrease was not consistent from one measurement to the next because of peristalsis. To smooth the data a running average over three times was calculated. The time for the maximum area to decrease by half was estimated as a measure of gastric emptying. Comparisons were made between controls and between control and saline and control and dopamine using paired *t* tests. No significant differences were found.

There is considerable day-to-day and time-related variability in gastric emptying measured ultrasonographically. A 2 h dopamine infusion at 3 μg kg min^{-1} did not significantly slow gastric emptying measured with this method.

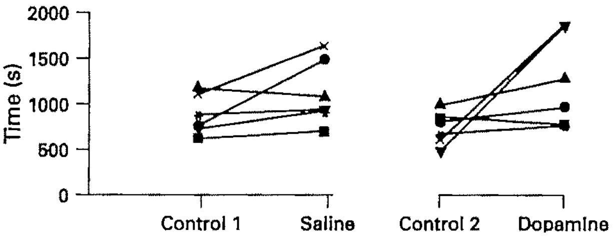

Figure 4 Time for antral area to fall to 50% of maximum (three point moving average).

Modelling the photographic "restricted window" to derive "true glottic view"

P. Groom*, J. Talbot*, and P. Charters
Department of Anaesthesia, Aintree Hospitals, Liverpool, and Department of Medical Illustration, Aintree Hospitals, Liverpool

The perceived view of the glottis results from panning multiple "eyelines" to construct a composite panoramic image, the "true glottic view". In contrast, a still camera takes a single eyeline snapshot resulting in a partial view of the glottis, the "restricted window".[1] The aim of this study was to determine if it was theoretically possible, for a given laryngoscope blade, to use a restricted window photograph to derive the true glottic view. Line diagrams would be used to predict true glottic view and a restricted window and these measurements would be checked against photographic equivalents in a physical model.

An accurate acetate template for the shape of a Macintosh 4 laryngoscope blade was produced by progressive correction using computer graphics. This was superimposed on the upper incisors and glottis (fig. 5A) to determine the true glottic view. The restricted view was a parallel beam with lower border from incisors to the posterior glottis and upper border tangential to the lower lingual surface of the blade (fig. 5B). The photographic restricted window and true glottic view were determined using two equivalent eyelines in a physical model with a ruled scale (the glottis), the pointed edge of a transverse longitudinal bar (the incisors) and the same blade from which the template was constructed. Three variables were investigated: depth of blade insertion (90 to 130 mm), glottic depth (15 to 30 mm) and blade angulation (0 to 20 degrees). Angulation of the blade describes its rotation about the upper incisor.

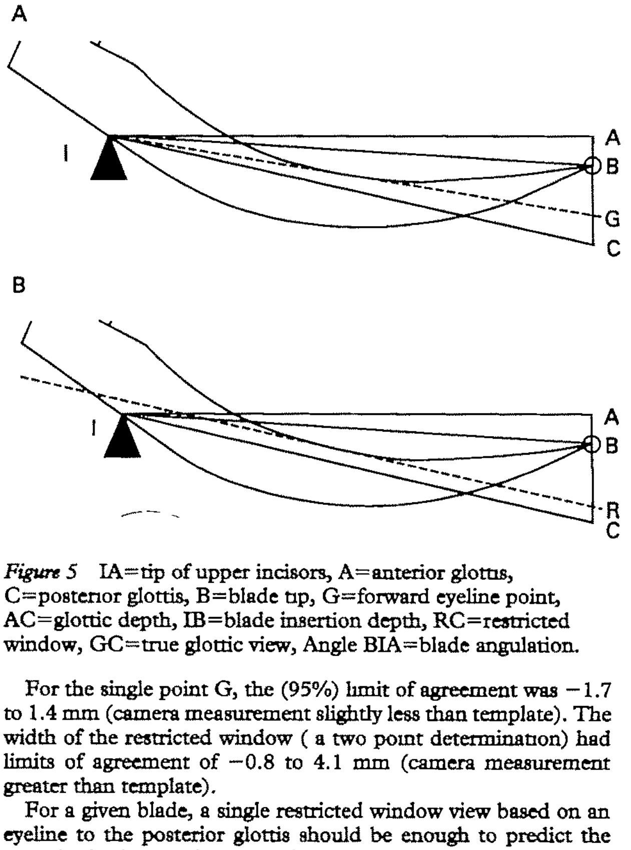

Figure 5 IA=tip of upper incisors, A=anterior glottis, C=posterior glottis, B=blade tip, G=forward eyeline point, AC=glottic depth, IB=blade insertion depth, RC=restricted window, GC=true glottic view, Angle BIA=blade angulation.

For the single point G, the (95%) limit of agreement was −1.7 to 1.4 mm (camera measurement slightly less than template). The width of the restricted window (a two point determination) had limits of agreement of −0.8 to 4.1 mm (camera measurement greater than template).

For a given blade, a single restricted window view based on an eyeline to the posterior glottis should be enough to predict the true glottic view (and also glottic depth). Apart from blade shape, the only other data needed are depth of blade insertion and blade angle, both of which are readily accessible.

Epiglottis modelling in a computer simulation of difficult laryngoscopy

M. Hawkins* and P. Charters
Department of Anaesthesia, Aintree Hospitals, Liverpool

A mathematical model for osseous factors in difficult laryngoscopy has been reported.[1] This recently formed the basis for a two dimensional computer simulation which depended on the position of the laryngoscope blade, and definable osseous constraints (e.g. degree of mandibular recession).[2] The eventual goal is an accurate three dimensional simulation including movements of soft-tissue structures. Contact of the laryngoscope blade tip with the hyoid is important for controlling elevation of the epiglottis.[3] It could be hypothesized that control of the epiglottis is lost proportionately as difficulty increases, that is the epiglottis gradually tilts posteriorly. Alternatively, if contact between the blade tip and hyoid is critical, loss of control may occur with minor degrees of difficulty, that is tending to let the epiglottis flop posteriorly, obstructing the view of the laryngeal inlet. The aim of this study was to determine epiglottis behaviour in this regard, to facilitate modelling in the simulation.

Lateral x-ray images of 25 volunteers undergoing laryngoscopy under topical anaesthesia were reviewed. Sixteen had been referred to the department, having been difficult in the past. The other nine were normal controls. On each image the following points were marked: I=tip of incisor; A=anterior glottis; P=posterior glottis; B=blade tip; E=tip of epiglottis. Angles were used for the analysis, as they are size independent. For the computer algorithms, it is convenient to model a theoretical straight-line blade. (This allows different blade shapes to be added later, but it does assume the tip is positioned similarly for each.) Of most interest is the relation between angles BIA and EAI. PIA and EIA were also measured as the glottis is obscured from view when PIA is less than EIA.

The plot for BIA (degrees) *vs* EAI (degs) appeared linear (see fig. 6).

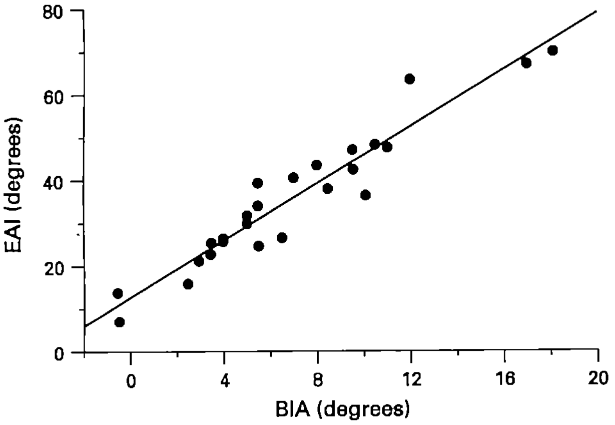

Figure 6 Relationship between EAI and BIA.

Equation for line,

$$\text{EAI (degrees)} = \frac{3.32\times\text{BIA}}{\text{(degrees)}+12.59}$$

Correlation coefficient, $r=0.955$

PIA range was 9.5–18 degrees (median=11.5, interquartile range=10.5–13.5 degrees). With increasing difficulty the view of the glottis was obscured and BIA=7 (degrees) appeared to be a cut-off point where PIA=EIA.

The results suggest that loss of control of the epiglottis is progressive.

Body posture during simulated tracheal intubation

A. J. Matthews*, C. J. H. Johnson* and N. W. Goodman
Department of Anaesthetics, Southmead Hospital, Bristol

Textbooks have pictures[1] of the best position of head and laryngoscope blade during tracheal intubation, but we could find no information on the best posture for the person performing the intubation. During our teaching of medical students, we thought that students tended to crouch more over patients, and to peer more closely. This is a report of a formal comparison of the posture of novices and skilled people during intubation.

We filmed (Canon E70 camcorder) intubation of a Laerdal intubation manikin on a standard fixed height operating theatre trolley during two intubations by each subject. For the first we filmed left side-on, and for the second end-on. We asked the subjects to tell us when the tracheal tube was in the larynx. For some subjects, we took a close-up of the hand-grip on the laryngoscope. Filming was done by one investigator (CJ) in as near standard positions as possible, using a tripod.

Three video frames were captured at the "moment" of intubation (Macintosh Performa 5300, SimpleText) for each subject: side-on, end-on, grip. Another investigator (N.G.) anonymised and coded the images (GraphicConvertor v2.5), before the third investigator (T.M.) analysed them from colour hard copy (Epson StylusColor 500) or screen images (NIH Image v1.52). Elbow angle and distance from subject's nose to manikin's chin were the two primary variables. We also measured the angle at the shoulder (nose-shoulder-elbow). Nose-chin was converted to true distance. The results are presented as median and interquartile range and compared using the Mann-Whitney *U* test (StatView SE v 1.4) (table 5).

We studied 17 skilled (eight consultants, nine trainees) and 15 novices (nine medical students, four surgical trainees, two trainee operating department personnel).

Elbow angle ($P<0.01$) and nose-chin distance ($P=0.01$) were smaller for the novices; shoulder angles were not significantly different ($P=0.19$). There were too many different hand-grips for any objective measures, but the novices were more likely to hold the laryngoscope further from the hinge. Novices were also more likely to have their forearm below the horizontal; four novices had their elbow on the trolley.

Table 5 Angles at elbow and shoulder, and distance from subject's nose to manikin's chin, during tracheal intubation of an intubation dummy. Medians (interquartile range)

	Elbow angle	Nose-chin (cm)	Shoulder angle
Skilled	108°	43	43°
	(99–120)	(41–56)	(38–47)
Novices	92°	37	39°
	(88–102)	(25–41)	(33–42)

We conclude that there are systematic differences in the way skilled people and novices stand during tracheal intubation. Undoubtedly intubation was more difficult for the novices, and we do not know whether crouching was because of difficulty, or whether the difficulty was caused by crouching. It may be that skilled people are more likely to crouch for a difficult intubation. However, for simple mechanical reasons keeping the arm more straight encourages lifting of the laryngoscope and bending the elbow encourages levering of the laryngoscope.

Bolus doses of alfentanil prevent the increase in Pa amplitude associated with intubation in a dose-dependent manner

G. Skinner*, R. M. Sharpe*, C. Shannon*, C. Thornton, C. J. Doré and M. D. Brunner
Department of Anaesthesia, Northwick Park Hospital, Middlesex

The amplitude of the early cortical wave, Pa, of the auditory evoked response (AER) decreases with increasing hypnosis[1] and increases after a stimulus, for example intubation[2], indicating arousal. Alfentanil infusions block the increase in Pa amplitude associated with intubation in a dose-dependent manner.[3] This study investigated the effect of bolus administration of alfentanil on Pa amplitude in response to intubation.

This study was approved by the local Ethics Committee. Forty-five unpremedicated ASA I or II patients, aged 18-65 yr, gave written informed consent. Anaesthesia was induced with propofol 2 mg kg^{-1} and vecuronium 0.1 mg kg^{-1} and the lungs ventilated for 15 min with 50% nitrous oxide in oxygen to 0.6 MAC end-expiratory isoflurane using a laryngeal mask airway (LMA). Normocapnia was maintained. They were then allocated randomly into three equal groups. Group A received saline (control), group B, alfentanil 15 $\mu g\ kg^{-1}$ and group C, alfentanil 50 $\mu g\ kg^{-1}$. The bolus doses were given 1 min before the LMA was removed and the patients' tracheas were intubated; this reflects the distribution time for alfentanil from plasma to brain. The early cortical AER in response to a 6 Hz click stimulus was recorded from forehead and mastoid electrodes throughout. AER data corresponding to 2.6 min before administration of alfentanil or saline and after intubation were analysed and compared.

The change in Pa amplitude after intubation was determined for each group. One-way analysis of variance was performed after $\log_{10}$ transforming the data and the group means were tested for linearity.

After intubation (fig. 7), Pa amplitude increased in the control group A by 60% (+10 to +130, 95% CI) and decreased in the alfentanil groups; group B by 11% (−38 to +29, 95% CI) and group C by 26% (−49 to +7, 95% CI). There were significant ($P<0.005$) linear trends in the three group means for Pa amplitude.

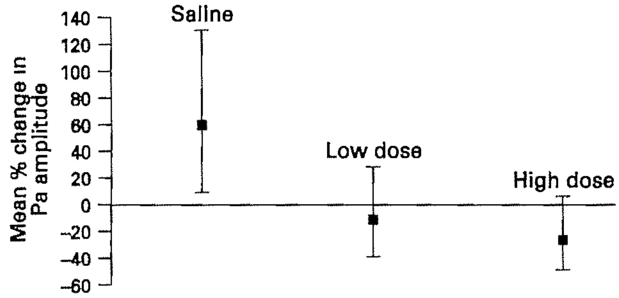

Figure 7 Mean percentage change in Pa amplitude after intubation (95% CI) in the three groups.

We have demonstrated that the increase in Pa amplitude associated with tracheal intubation was blocked by bolus administration of alfentanil, 60 s before intubation.

Preoperative education reduces side effects when patient-controlled analgesia is used

M. J. Griffin, L. Brennan and A. J. McShane
Department of Anaesthesia and Intensive Care, St Vincent's Hospital, Dublin

Patient-controlled anaesthesia (PCA) is a relatively new means of analgesia administration which has many theoretical advantages. However, a significant number of patients using PCA obtain inadequate pain relief and have significant symptoms ascribed to PCA resulting in premature termination and poor results. Anxiety and poor coping skills are predictors of postoperative pain[1] and may be reduced by education. This study determined the effect of detailed preoperative education on postoperative PCA use, pain, patient satisfaction, side effect profile and antiemetic use.

Eighty-five patients undergoing major procedures were allocated randomly to group A (special tuition) or group B (no special tuition). Written consent was obtained from group A patients ($n=42$) who received detailed preoperative education including standardized in depth explanation of PCA and a visual demonstration. Group B patients ($n=43$) consented to postoperative pain and satisfaction score assessment, a chart review and received non-standardized information from their anaesthetist at the preoperative visit. Visual analogue scale (VAS) assessment of pain and satisfaction, morphine consumption, side effects, antiemetic use and rescue analgesia requirement were recorded in recovery, and at 6 h, 24 h and 48 h. Statistical analysis of morphine consumption, pain and satisfaction scores was performed using the Mann-Whitney *U* test. Side effects, antiemetic and rescue analgesia requirements were compared with the chi-square test.

Both groups had similar morphine consumption, pain and satisfaction scores at all stages. Pain scores were low and satisfaction scores were high throughout in both groups. Group A demonstrated significantly greater antiemetic use at 6 h and 24 h ($P<0.05$) and significantly less nausea and vomiting at 24 h ($P<0.05$). Twelve group A patients and 22 group B patients complained of nausea by 24 h. At 6 h, 12 group A patients and five group B patients had requested antiemetic medication. At 24 h, 15 group A patients and eight group B patients had requested an antiemetic.

PCA results in excellent analgesia and a high degree of satisfaction irrespective of the intensity of preoperative tuition. Preoperative PCA tuition seems to result in more sensitive and efficient use of antiemetic medication and an improved side effect profile. Warning patients in advance of these side effects and how to deal with them may result in more efficient and effective use of PCA.

Assessment of neuromuscular monitoring by intensive care nurses: comparison of the TOF-watch and tactile assessment

R. Greer*, A. J. Pearson and N. J. N. Harper
Intensive Care Unit, Manchester Royal Infirmary, Manchester

Neuromuscular monitoring of ICU patients is important because the action of these drugs varies greatly in this population. Tactile assessment of train-of-four (TOF) is used commonly to assess the degree of block . Acceleromyography uses the principle that the acceleration of a muscle is proportional to the force of contraction (Newton's second law). The TOF-watch is a new, compact device for monitoring neuromuscular block by means of acceleromyography.

In patients with steady state neuromuscular block our aims were: (1) to investigate the ability of ICU nurses to assess the number of TOF twitches, and (2) to investigate the ability of nurses to detect tactile TOF fade and assess the TOF ratio.

We investigated 20 stable, sedated, adult patients receiving an infusion of atracurium. The nurse in charge of the patient (nurse A) made a tactile TOF assessment and then made a TOF-watch measurement. Four subsequent tactile assessments were made immediately by different nurses who were blinded to the TOF-watch result. At the same time as the tactile assessment, nurse A made a TOF-watch assessment. One minute elapsed between measurements.

Nurses incorrectly assessed the number of TOF twitches in approximately 50% of estimates (fig. 8).

A Bland and Altman plot demonstrated bias such that the nurses tended to overestimate the TOF ratio.

Nurses tend to underestimate the degree of block when assessing the TOF ratio in the ICU.

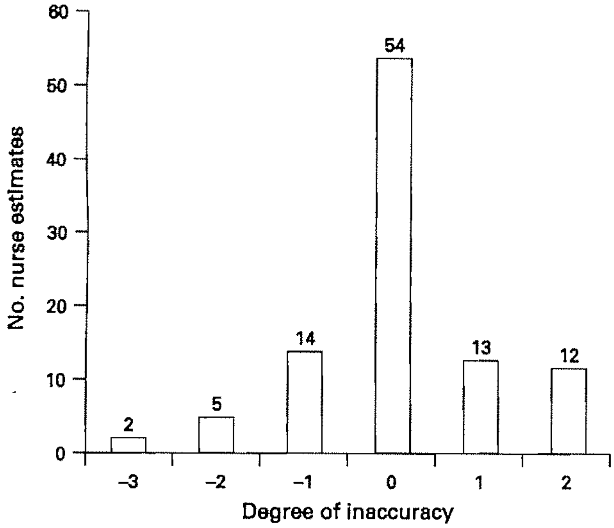

Figure 8 Degree of inaccuracy for nurses estimating TOF twitch count.

Effect of music on the psychomotor performance of anaesthetists

C. R. E. Hawksworth*, P. Sivalingham* and A. J. Asbury
Department of Anaesthesia, Western Infirmary, Glasgow

Playing music in the operating theatre is commonpace in the U K. A recent survey showed most anaesthetists feel this is generally not distracting.[1] Self-chosen music has a beneficial effect on the mental performance of surgeons.[2] We undertook this study to determine if music affected anaesthetists' psychomotor performance.

Twelve anaesthetists took part in this study. Subjects performed two tests from the PsychE computerized psychomotor evaluation programme developed in this department. After practice runs with both tests, subjects wore padded headphones and were asked to perform each pair of tests four times while listening to Pachelbel's Canon in D, their own self-chosen music, "white noise", or silence. The order in which the music was played was determined by a 4X4 orthogonal Latin square design to counter cross-over effects. The first test was the numeric vigilance test. Three-digit numbers were presented on the computer screen at a rate of 100 per minute. Each number differed randomly from the previous number by one digit. Eight per cent of these numbers were duplicates of the previous number. Subjects were asked to identify these duplicates by pressing the keyboard spacebar when they occurred. Correct responses, missed duplicates and superfluous responses were recorded.

The second test was a dual test — tracking and simple reaction time. The primary task was to use the computer mouse to follow a randomly moving target on the screen with a cursor. The percentage of time the cursor was on target was recorded. The secondary task was to identify the random appearance of a yellow symbol on the screen by pressing the spacebar. The time taken to press the spacebar was recorded.

We were unable to demonstrate a difference in the scores obtained under any of the music conditions using Friedman's test for non-independent repeated measures (table 6). This implies that anaesthetists' psychomotor performance under laboratory conditions is not affected by music. However, this may not necessarily apply in theatre conditions.

POSTER PRESENTATIONS

Buscopan does not improve pain after laparoscopic sterilization

C. M. Wilson*, N. Lillywhite*, S. Wiltshire* and P. Mills*
Department of Anaesthesia, Ipswich Hospital, Ipswich

Laparoscopic sterilization is performed frequently as a day-case procedure. Smooth muscle spasm induced by clips placed on the Fallopian tubes may be an important cause of postoperative pain. A study from this institution has shown that glycopyrronium (anticholinergic and antispasmodic agent) improves pain scores after laparoscopic sterilization.[1] Buscopan is used to relieve smooth muscle spasm in radiological investigation.[2] We investigated the effect of i.v. buscopan on pain scores, analgesia requirements and the incidence of nausea and vomiting after laparoscopic sterilization.

Forty-five patients were studied in a prospective randomized study. Patients were premedicated with diclofenac 100 mg p.r. Anaesthesia was induced with midazolam 2 mg, fentanyl 100 µg, droperidol 0.625 mg and a sleep dose of propofol. Anaesthesia was then maintained with oxygen, nitrous oxide and 1–2% enflurane via a laryngeal mask airway. Patients were then randomized to receive either placebo or buscopan 20 mg i.v. before the start of surgery. Postoperative analgesics were administered at patient request; co-dydramol two tablets orally or morphine 10 mg i.m. Prochlorperazine 12.5 mg was given as required for nausea. Pain and sedation scores were assessed by a blinded observer on admission to recovery and at 1, 2 and 3 h after operation. Incidence of nausea and vomiting and any analgesic or antiemetic drugs given were also recorded. Data were analysed with parametric and non-parametric tests as appropriate, with $P<0.05$ taken as statistically significant.

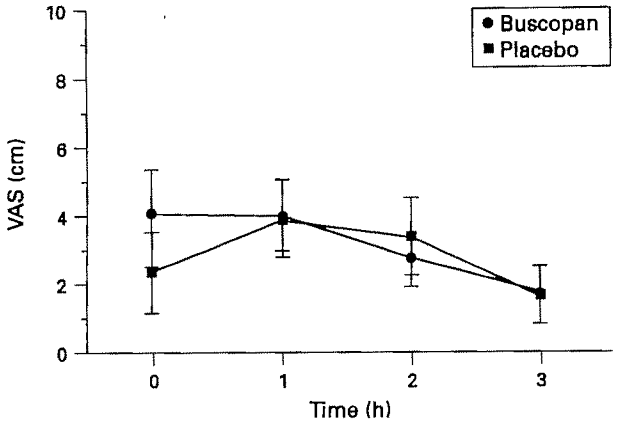

Figure 9 Pain scores (mean (95%) CI) at 0, 1, 2 and 3 h after operation.

The main findings are shown in figure 9. There were no significant differences in pain scores, sedation or nausea and vomiting between the two groups.

We conclude that buscopan 20 mg i.v. did not improve pain after laparoscopic sterilization.

Halothane decreases K^+ evoked glutamate release from rat cerebrocortical slices

B. Nicol*, D. J. Rowbotham and D. G. Lambert
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

We have shown previously that ketamine and thiopentone decreased K^+ evoked glutamate release from rat cerebrocortical slices.[1] As there are conflicting reports of the effects of halothane on evoked glutamate release[2 3] we have examined the effects of this agent on K^+ evoked release from rat cerebrocortical slices.

Cerebrocortical slices (350 µm×350 µm) were cut from Wistar rats. The slices were suspended in oxygenated (95% oxygen/5% carbon dioxide) Krebs buffer, pH 7.4, for 40 min before loading into a perfusion chamber.[1] The slices were perfused at 1 ml min^{-1} for 60 min. A 2 min pulse of 46 mmol $litre^{-1}$ K^+ (Na^+ adjusted) was then applied (S_1). A second pulse of K^+ (S_2) was applied after a further 40 min of perfusion. Slices were exposed to halothane (mean 85 SEM 6), 222 (4) and 395 (16) µmol $litre^{-1}$, equivalent to 0.24, 0.61 and 1.09 rat MAC) immediately after S_1 until the end of the experiment via a precalibrated Fluotec 3 vaporizer. Aqueous halothane concentrations stated were measured by gas chromatography. Glutamate concentrations were measured fluorimetrically.[1] Area under the stimulation curves (S_1 and S_2) was estimated and the S_2/S_1 ratio calculated. The effect of halothane on the control S_2/S_1 ratio was analysed by Wilcoxon rank sum test and considered significant when $P<0.05$. All data are mean (SEM). K^+ produced monophasic release of glutamate during S_1 and S_2 (fig. 10) yielding an S_2/S_1 ratio of 1.06 (0.12) (n=12) under control conditions. The S_2/S_1 ratio was reduced by 34 (7)% (n=5, $P<0.05$), 48 (8)% (n=6, $P<0.05$) and 63 (7)% (fig. 10, n=6, $P<0.05$) with 0.24, 0.61 and 1.09 rat MAC halothane, respectively.

Collectively these data support an inhibitory effect of halothane on K^+ evoked glutamate release. The mechanism(s) of this inhibitory effect is currently under investigation.

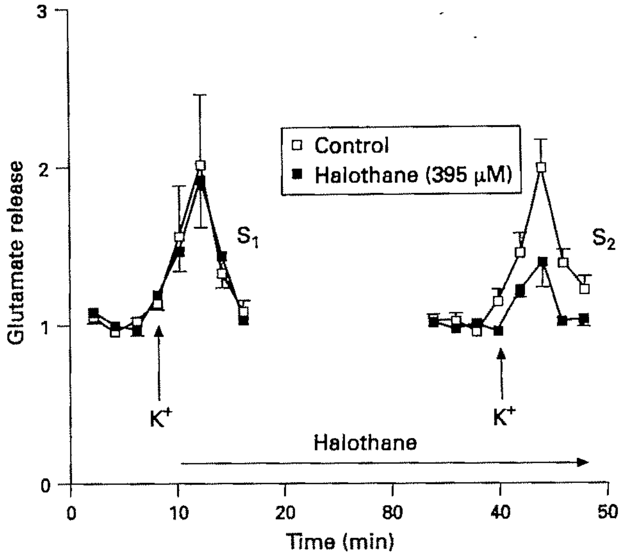

Figure 10 Halothane (1.09 rat MAC) inhibited K^+ evoked glutamate release. Glutamate release is expressed relative to the mean of the first three basal samples.

Preliminary survey into clinical attitudes to computer based decision support systems

P. C. W. Beatty
University Department of Anaesthesia, Manchester Royal Infirmary, Manchester

Computer based decision support systems promise to be able to offer clinical staff new alarm systems, better detection of critical incidents and on-line advice on treatment strategy. However, such systems will not be used unless their designs meet the preferences, prejudices and expectations of the clinical staff. To investigate these clinical attitudes, we conducted a preliminary survey of medical and non-medical clinical staff in operating theatres, intensive care units and recovery at the Manchester Royal Infirmary.

A Likert style survey form was circulated to 81 anaesthetists (30 consultants, 51 trainees), 100 ICU nurses and 26 other members of staff including recovery nurses and ODA. Six questions with 12 choices concerning attitudes were asked. A separate section asked questions on profession, grade, experience, age and sex. Subjects were also asked to grade their access to/use of computers and computer literacy. Non-responders to the questionnaire were not followed up in this preliminary study so as to avoid potential bias of answers by giving extra information to subjects. The mean rate of return was 26.6%. The questionnaire included notes that were intended to give staff unfamiliar with the concept of such a computer based decision support system sufficient background information. All responses were pooled and the relative agreement/disagreement to choices within questions were examined using Friedman rank coefficients. Differences between groups were investigated using Mann-Whitney *U* testing, with the responses divided between medical and non-medical staff and alternatively those specializing in general anaesthetics or ICU. Finally, responses to choices were grouped by underlying "issue" using factor analysis.

All responders favoured characteristics in systems that advise or guide rather than control. Consistently, the non-medical group were more prepared to give control to computer systems than were their medical colleagues. This bias reached statistical significance in the case of nine choices in three questions ($P<0.05$). There were no consistent differences between the ICU and general anaesthetics groups, although four choices in three questions did show significant differences. Responses indicated that staff welcomed the idea of detailed advice on treatment off-line, preferably through flow diagrams, but wanted on-line advice limited to alarms, which should be more sophisticated. The opinion that should be used for such advice should be drawn from as wide a group of experts as possible. Extra physiological measurements would be welcomed. Responders wanted the systems to compensate for failures of vigilance.

The attitudes of responding clinical staff are consistent with other studies on operator confidence in computer systems.[1] As the rate of return was low, this preliminary study must be validated by repeating the questionnaire with follow up on a wider basis.

Effects of ketamine on cAMP formation in Chinese hamster ovary cells expressing recombinant opioid receptors

K. Hirota, B. L. Appadu, D. K. Grandy*, L. A. Devi* and D. G. Lambert
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester, Vollum Institute, Oregon, USA and Department of Pharmacology, New York University Medical Center, USA

Ketamine has been reported to interact with opioid receptors and to produce analgesia.[1] Opioid receptor agonists inhibit adenylyl cyclase thereby reducing cAMP formation.[2] We have reported that ketamine interacts stereoselectively with opioid receptors with a rank order potency of $\kappa>\mu>\delta$.[3] However, these studies provide limited information as to the nature of the interaction. To consider this question we have examined the effects of ketamine on cAMP formation in Chinese hamster ovary (CHO) cells expressing recombinant κ, μ an δ (CHOκ, μ and δ) receptors, respectively.

CHOκ (passage 5–8), CHOμ (passage 13–16) and CHOδ (passage 7–10) cells were maintained in supplemented Hams F12 medium. All experiments were performed using whole cells at 37°C in 0.3 ml of Krebs/HEPES buffer, pH 7.4 containing isobutylmethylxanthine 1 mmol litre^{-1}. The effects of ketamine were examined on forskolin (10 μmol litre^{-1}) stimulated and spiradoline, [D-ala^2, MePhe^4,Gly(ol)^5]enkephalin (DAMGO) and [D-Pen^{2,5}]enkephalin (DPDPE) inhibition of forskolin stimulated cAMP formation in all cell types. All data are mean (SEM) ($n \geq 4$).

Spiradoline 2.0 nmol litre^{-1}, DAMGO 100 nmol litre^{-1} and DPDPE 5.0 nmol litre^{-1} inhibited forskolin stimulated cAMP formation in CHOκ, CHOμ and CHOδ cells by 28.8 (3.1), 36.8 (2.4) and 41.1 (1.9)% respectively. Ketamine produced a dose-dependent naloxone (10 μmol litre^{-1} insensitive inhibition of cAMP formation in all cells, including untransfected CHO cells (table 7). Co-incubation of ketamine (1 mmol litre^{-1}) and subtype selective agonists was neither additive nor synergistic.

These data demonstrate that ketamine inhibited adenylyl cyclase but that this inhibition was not mediated by the opioid receptor. Despite our previously reported interaction of ketamine with opioid receptors other non-opioid mechanism(s) are likely to underlie ketamine analgesia.

Table 7 Log molar concentration of ketamine producing 50% inhibition (pIC_{50}) of cAMP formation in CHOκ, μ and δ cells Mean value (mmol litre^{-1}) quoted in parentheses. (CHOwt cells are untransfected)

	CHOκ	CHOμ	CHOδ	CHOwt
pIC_{50}	2.576±0.050 (2.65)	2.684±0.051 (2.07)	2.694±0.086 (2.02)	2.696±0.054 (2.01)

Effect of sevoflurane on spontaneous sympathetic activity and baroreflexes in rabbits

D. Ma*, S. M. Sapsed-Byrne*, M K. Chakrabarti and J. G. Whitwam
Department of Anaesthesia, Royal Postgraduate Medical School, Hammersmith Hospital, London

Previous studies, in humans and animals, showed that while sevoflurane was not associated with major significant changes in heart rate (HR) and sympathetic nerve activity,[1 2] it caused a concentration-dependent reduction in arterial pressure.[3] We have studied the potential role of baroreflexes on its effects.

Sixteen New Zealand White rabbits were anaesthetized (methohexitone bolus 10–15 mg.kg^{-1} and 1% α-chloralose 15–20 mg kg^{-1} h^{-1} i.v.), paralysed (suxamethonnium 10 mg i.v. every 20–30 min) and their lungs ventilated mechanically. Blood-gas tensions and pH*a* and oesophageal temperature were kept within normal limits. Fascicles of renal sympathetic nerves were exposed, desheathed, cut distally, immersed in a mineral oil pool and mounted on electrodes for recording renal sympathetic nerve activity (RSNA). The preparations were divided randomly into three groups: in group 1 ($n=7$) sevoflurane was administered at 1%, 2%, 3% and 4% end-tidal concentration each for 20 min; group 2 ($n=4$) received an infusion of sodium nitroprusside (SNP) for 60 min to lower mean arterial pressure (MAP) to 30–40 mm Hg; group 3 ($n=5$) was used to observe baroreflex sensitivity by using arterial depressor and pressor tests with bolus injections of either SNP 2, 4, 8 and 16 μg kg^{-1}) or phenyleprine 0.5, 1, 2 and 4 μg kg^{-1} before and after 1% and 2% sevoflurane administration. Baroreflex sensitivity was evaluated by deriving the relation between ΔHR, ΔRSNA and ΔMAP in response to SNP-induced hypotension and phenyleprine-induced hypertension, and also by calculating the ratio of the maximum changes in HR and RSNA to the maximum changes in MAP (ΔHR/ΔMAP; ΔRSNA/ΔMAP) produced by the largest dose of 16 μg kg^{-1} of SNP and 4 μg kg^{-1} of phenyleprine, respectively.

At similar mean MAP values between 40 and 80 mm Hg, SNP caused statistically significant increases in HR from 249 beats min^{-1} to 292 beats min^{-1} ($P<0.05$) and RSNA by 150% ($P<0.05$); sevoflurane up to 3% did not change RSNA which decreased to 63% of control values at 4% ($P<0.05$), without any significant change in mean HR from a control value of 246 beats min^{-1}. Baroreflex sensitivity was attenuated by sevoflurane expressed as relationship curves between ΔHR , ΔRSNA and ΔMAP, and also expressed as the ratio of ΔHR/ΔMAP and ΔRSNA/ΔMAP.

Sevoflurane depresses the baroreflex sensitivity. However, depressed baroreflexes continue to compensate for the depressant effect of sevoflurane on sympathetic activity up to 3% and on cardiomotor activity up to 4% concentration.

Absence of memory for intraoperative information

Sir,—I wish to comment on the article by Russell and Wang on absence of memory for intraoperative information during surgery under adequate general anaesthesia.[1]

Their study seemed to have been motivated by their belief that the brain can only process information during anaesthesia if anaesthesia is inadequate enough to result in the patient being conscious. Using the isolated forearm technique (IFT), they showed that there was no evidence for explicit recall, or implicit memory changes in patients, for times at which these patients were unresponsive to verbal command.

I would agree that changes in implicit memory are more likely to occur at times when the anaesthetized patient is responsive to verbal command, but their assumption that an observed response when using the IFT automatically indicates a state of consciousness is, I believe, not warranted.

As they themselves quoted, with some general anaesthetic techniques more than 70% of patients may be capable of responding to commands during surgery (using IFT), with no postoperative explicit recall of intraoperative events. It is still not necessarily the case however, that the patient was conscious, even if postoperative changes in implicit memory are demonstrated in these patients. All this implies is that the brain has processed information in some way and created a response.

The authors seem to believe that IFT acts as a reliable "consciousness monitor" or indicator of "adequate" anaesthesia, but they disregard the possibility that responses observed while using this technique might also reflect pre-conscious information processing. In other words, whereas patients might respond appropriately, they might still not be conscious.

The major fault with this study is that in attempting to disprove the notion of pre-conscious information processing, they make use of a clinical tool (IFT) which, much of the time, may in fact measure exactly what they wish to disprove.

Until when, and if, it is demonstrated that this type of anaesthesia results in significant psychological morbidity, there is no reason to suppose that it is not "adequate".

1. Russell IF, Wang M. Absence of memory for intraoperative information during surgery under adequate general anaesthesia. *British Journal of Anaesthesia* 1997; 78: 3–9.

Sir,—Dr Hooper speculates on our motives for conducting this study.[1] The background is the voluminous literature apparently demonstrating implicit learning during general anaesthesia.[2–4] Typically, these studies involve the use of neuromuscular blocking agents and absence of systematic intraoperative monitoring of levels of consciousness. Given the poor relationship between intraoperative cognitive function and postoperative explicit recall,[5] it is quite possible that in many of these studies intraoperative information was presented to patients who were wakeful. Our study demonstrated that when level of consciousness is controlled such that there is insufficient higher cortical function to allow response to command, verbal learning (whether explicit or implicit) is precluded.

Dr Hooper's use of the terms "conscious" and "unconscious" is misleading, because it assumes two discrete states. The evidence generated by interest in memory and awareness during anaesthesia over the past decade[2–4] demonstrates that we have a continuum, which can be delineated in terms of various experimental paradigms.

Dr Hooper's letter also implies the common misconception that absence of postoperative recall is synonymous with intraoperative oblivion, and therefore "adequate anaesthesia". Readers who have clinical experience of patients with dense amnesic states such as Korsakoff's psychosis need no persuading of the mistake in this assumption. Memory function in such patients is irreversibly impaired such that memory of moment-to-moment experience is not maintained beyond a few minutes. However, it would be wrong to characterize them as having impairment of *consciousness*: all other cognitive functions may be normal, they are commonly alert and have a clear sensorium. The relevance of this for anaesthetists is that many drugs used in general anaesthesia have precisely these types of effects on memory function, albeit in a reversible manner.[6]

We are unclear as to what Dr Hooper means by "pre-conscious processing". Normally this term refers to *perceptual* processes which occur without the involvement of higher cortical function. We are certainly not attempting to dispute the existence of such processes. However, it is incorrect to suggest that specific motor responding to a verbal command is purely a function of pre-conscious processing. Response to command, particularly if that command involves conditional clauses such as "if you are in pain, squeeze your fingers twice" clearly involves operation of higher cortical centres. It seems that Dr Hooper is attempting to use the term "pre-conscious processing" as a semantic device with which to dismiss the significance of high levels of intraoperative cognitive processing.

Sevoflurane or halothane for paediatric endoscopy

Sir,—We were interested in the conclusion of Meretoja and co-workers in their article comparing halothane with sevoflurane for paediatric endoscopic procedures.[1] We have recently undertaken an audit of sevoflurane, as a new drug, in this anaesthetic department and found that in a study of 344 adults and children, only two patients complained of nausea or vomited in the recovery area after administration of sevoflurane. An analysis of the patients in our audit by the ages used in the study of Meretoja and colleagues showed that of 17 patients aged 3–11 months, 92 patients aged 1–5 yr and 14 patients aged 6–15 yr who received sevoflurane for induction and maintenance of anaesthesia, only two patients in the middle age group vomited. A total of 20 patients aged 3–11 months, 243 patients aged 1–5 yr and 66 patients aged 5–16 yr (with 15 adult patients) also received sevoflurane for maintenance of anaesthesia with no additional patients suffering nausea and vomiting. All paediatric patients are kept in the recovery area for a minimum of 30 min and those patients treated in the day surgery facility were observed for a minimum of 1 h in recovery after anaesthesia and for a minimum of an additional 1 h before discharge.

The observation that a relatively short administration of sevoflurane may confer antiemetic properties, similar to those of propofol,[2] in the postoperative period has been confirmed by other authors and our audit.[3-5] A recent study comparing propofol and sevoflurane found that the incidence of nausea and vomiting was higher in patients receiving sevoflurane than in those receiving propofol, but this finding was not present in earlier work from this group.[6 7]

We also noted an emergence phenomenon similar to that reported by Johannesson, Floren and Lindahl; 19 of 329 children in our audit were observed to be "distressed", "restless" or "agitated" in the recovery area.[3] There were no long-term adverse sequelae.

We would support the conclusion of Merotoja's group that further studies are indicated to confirm (and quantify) any antiemetic properties of this new volatile agent.[1]

Spinal anaesthesia: effect of the site of injection on the spread of analgesia

Sir,—I read the article by Veering and co-workers[1] with much interest. In their study they examined the effect of the site of injection on analgesia levels after spinal injection of 0.5% hyperbaric bupivacaine solution. The patients received 3 ml of 0.5% hyperbaric bupivacaine for spinal anaesthesia either at the L3–4 (group 1) or L4–5 (group 2) interspace. The highest analgesia levels in their study did not differ between groups.

In my opinion, the results of their study are not as disappointing as the authors claim. Admittedly, the results of their study showed that the difference in the level of maximal spread of analgesia between the two groups was not statistically significant. However, if we examine the results of their study more closely, we note an interesting difference, in group 1 (L3–4), six of 15 patients developed the highest level of analgesia to the fifth thoracic dermatome or higher, compared with only two of 15 patients in group 2 (L4–5). Although this may be a biased approach, it is nevertheless a high sensory level of spinal anaesthesia that should be avoided, as patients are at increased risk of developing hypotension. Therefore, it is probable that the small statistically insignificant difference in maximum decrease in SAP occurred in this group of patients.

On the other hand, one patient in group 2 developed the highest level of analgesia to the T12 dermatome, which was probably insufficient for blocking the pain caused by bladder distension during surgery.

It is a pity that the authors did not include an additional higher level of subarachnoid puncture in their study. There may have been a difference in the sensory level of analgesia between injection of the local anaesthetic solution at the L4–5 interspace compared with injection at the L2–3 interspace.

In my opinion, when we perform spinal anaesthesia we should try to choose a higher approach to the subarachnoid space (preferably L2–3) and give less local anaesthetic. This could result in better control of spread of analgesia in decreasing the number of patients with too high and too low analgesic levels after spinal anaesthesia.

M. Kamenik
Department of Anaesthesiology, Intensive Care and
Pain Management
Maribor Teaching Hospital,
Ljubljanska, Maribor, Slovenia

1. Veering BTh, Riet PM, Burm AGL, Stienstra R, Van Kleef JW. Spinal anaesthesia with 0.5% hyperbaric bupivacaine in elderly patients: effect of site of injection on spread of analgesia. *British Journal of Anaesthesia* 1996; 77· 343–346.

Sir,—Thank you for the opportunity to respond to the comments of Dr Kamenik on our article.[1] As noted, the highest levels of analgesia after injection via the L3–4 and L4–5 interspaces did not differ. In his comments Dr Kamenik draws attention to the fact that six of 15 patients who received injection via the L3–4 interspace had the highest analgesia levels extending to T5 or higher compared with only two of 15 patients who received the injection via the L4–5 interspace. Furthermore, Dr Kamenik relates the higher incidence of high thoracic analgesia levels to the slightly larger, although not statistically significant, decrease in systolic arterial pressure in patients who received the injection via the L3–4 interspace.

The question which must be addressed in this respect is whether or not we might have missed a true difference in the levels of analgesia associated with injection via the L3–4 and L4–5 interspaces. As noted in the article, the study was based on a power analysis of earlier observations, and aimed at an 80% probability of detecting a difference of two segments, which we considered clinically relevant. This includes a 20% probability of missing a true difference of two segments, which is generally considered acceptable from a statistical point of view. Of course, the probability of missing a true difference of one segment is considerably greater. In this respect the comments of Dr Kamenik may be justified. However, as his comments are based on isolated observations, these are highly speculative and should be tested prospectively, possibly by a study aimed at the number of patients reaching analgesia levels in the high thoracic region. The same is true for his comment on the single patient in whom the analgesia level was restricted to T12.

We did not include a group of patients receiving injection via the L2–3 interspace because an earlier study revealed no difference in analgesia levels after injection via the L2–3 and L3–4 interspaces.[2] In addition, the injection sites were selected on anatomical considerations, as described previously and discussed in our article. Briefly, hyperbaric solutions, under the influence of gravity, migrate preferentially to the lower levels of the subarachnoid space (i.e. below L3 to T4 in the lumbosacral concavity and above L3 to L4 in the thoracic concavity).[3 4] As such it is expected that injection of a hyperbaric solution via the L2–3 interspace with the patient in the sitting position during injection and until 2 min thereafter, followed by horizontal supine positioning, would result in higher analgesia levels than injection via the L4–5 interspace.

Overall, inter-individual variation in analgesia levels after subarachnoid injection of hyperbaric bupivacaine solutions is impressive, especially in elderly patients. Any modifications in the spinal procedure that could reduce this variability and prevent excessive cephalad spread of the local anaesthetic solutions, and thereby result in a more predictable and safer spinal block, would be welcome. The suggestion of Dr Kamenik to reduce the dose of local anaesthetic may deserve investigation.

Cuff deflation for easier weaning from ventilation

Sir,—We read the editorial by Shneerson[1] with great interest and agree that much work needs to be done to assess the relative importance of each of the new approaches during the weaning process.

Shneerson stated that cuff deflation is probably the single most underrated and important step in improving upper airway function and should have a central place in the preparatory phase of weaning. The reason cited is that deflation of the cuff improves the co-ordination of the laryngeal and pharyngeal muscles by re-instating the respiratory function of the larynx and by allowing patients to speak.

The above explanation is logical; however, another immediate advantage of deflating the cuff is reduced work of breathing, allowing easier weaning. During quiet breathing, intrapleural pressure at the base of the lungs varies between −2.5 mm Hg and −6 mm Hg.[2] However, if an adult breathes through a size 9.0 mm internal diameter (id) tracheal tube, peak intrapleural pressure developed during normal inspiration is approximately −15 mm Hg,[3] indicative of increased work load of breathing. A size 8.0 or 9.0 mm id tracheostomy tube should also produce changes of similar magnitude. Although these changes seem modest, in patients with weaning problems they could be clinically important. Even a small reduction in work load of breathing could be crucial in determining the outcome in such patients.

Deflation of the cuff allows the patient to breathe both through the lumen and also from around the tube. This leads immediately to a significant decrease in the resistance and work load of breathing. The fact that patients are able to phonate is evidence of the higher resistance offered by the tracheostomy tube compared with the rest of the upper airway. Speech would not be possible if the resistance of the tracheostomy tube was much less than that offered by the upper airway, as this would allow the air to escape through the tracheostomy tube, taking the path of least resistance.

Sleep deprivation in intensive care during the recovery phase is widespread and deserves further attention. Attempts should be made to establish a normal sleep–wake cycle. Generally patients in intensive care units are receiving constant rate infusions of sedatives and analgesics. Perhaps administration of sedatives to follow the circadian rhythm may help, so that during the night patients are well sedated and during the day, almost awake. Whether patients would benefit from such a strategy is open to question and needs further investigation.

3. Mushin WW, Jones PL. Flow of fluids through tubes: Resistance. In: *Physics for the Anaesthetist*, 4th Edn. London: Blackwell, 1987; 240–261.

Sir,—I thank Drs Bapat and Verghese for their comments. I agree that cuff deflation reduces the work of breathing and can enable patients to breathe spontaneously at an earlier stage in the weaning process. This benefit of cuff deflation is distinct from its use in improving upper airway function and is only of value when the patient is not attached to the ventilator. In contrast, upper airway coordination can be improved both when the patient is breathing spontaneously and while receiving ventilatory support. Cuff deflation can be used to achieve this, even before withdrawal of ventilatory support is attempted or between initial trials of this. These two benefits of cuff deflation, reduction of work of breathing and improvement in upper airway function, are therefore complementary and assist the weaning process in different ways.

Prophylaxis against deep vein thrombosis

Sir,—Wheatley and Veitch in their editorial on recent advances in prophylaxis against deep vein thrombosis stated that women receiving the combined oral contraceptive pill (OCP) should discontinue it 6 weeks before elective surgery.[1] While it is accepted that combined OCP users are at increased risk of venous thromboembolism, in the absence of other risk factors there is insufficient evidence to support a policy of routinely stopping the combined OCP before surgery.[2] A burden of responsibility is put on the person advocating stopping the combined OCP to arrange suitable alternative contraception. Failure to do so risks unwanted pregnancy, the effects of anaesthesia and surgery on an undiagnosed pregnancy and termination of pregnancy with its physical and emotional sequelae. The Royal College of Obstetricians and Gynaecologists Working Party report on thromboprophylaxis made three recommendations.[3]

(1) Patients receiving combined oral contraception should have a risk assessment profile performed, as with any patient undergoing gynaecological surgery.

(2) The combined oral contraceptive need not be ceased nor thromboprophylaxis commenced in women undergoing uncomplicated minor and intermediate procedures.

(3) Patients receiving combined oral contraception who are assessed as moderate risk should receive one of a variety of prophylactic measures. Whether it is necessary to cease oral contraception before surgery is unclear, but if this is done, adequate counselling regarding pregnancy risk or alternative contraception (e.g. progestogen only pill) should be provided. The situation with regard to the patient's additional risk factors should be considered on an individual basis.

Wheatley and Veitch also stated that hormone replacement therapy (HRT) has not been shown to increase the risk of thromboembolic disease. This is not accurate. Three recent studies have shown an increased risk of venous thromboembolism in users of HRT.[4–6] The risk of a blood clot increases from 1:10 000 per year in those not receiving HRT to 3:10 000 per year in those who are, so the effect of replacement treatment seems to be small. Assessing risk based on age and other risk factors still pertains.

Sir,—Dr Allsop is correct in highlighting an area of continuing controversy regarding thromboembolic prophylaxis for women taking the oral contraceptive pill (OCP). The report of the Royal College of Obstetricians and Gynaecologists Working Party[1] does not consider taking the OCP to be an independent risk factor for thromboembolic disease in patients undergoing surgery, but in combination with pre-existing risk factors it admits that there is uncertainty as to whether the OCP should be stopped before surgery. In contrast, the European Consensus Statement[2] regarded any woman receiving the OCP as being at an increased risk and therefore warranted either cessation of this medication 4–6 weeks before surgery or some type of prophylaxis. Obviously any woman who ceases to take the OCP must be advised to use adequate alternative contraception if she is to avoid the unquantified risk of unwanted/undiagnosed pregnancy and termination.

The three recent studies showing an increased risk of thromboembolic disease in women receiving hormone replacement therapy (HRT) were all published in the same edition of the *Lancet* after this editorial was written, and represent some of the first evidence that HRT may be associated with such a risk.

Intraocular pressure and suxamethonium

Sir,—After reading the case report of the use of rocuronium in a pregnant patient with an open eye injury by Gaiser and Seem,[1] I feel that it is necessary to comment on their recommendations concerning the avoidance of suxamethonium.

As in many situations there is a balance of risks to be sought before choosing any particular anaesthetic technique. In this case the authors decided that the risks of damage to the injured eye in using suxamethonium outweighed the risks of using rocuronium in a pregnant patient with a potential full stomach and a known increased incidence of difficult intubation.[2] But is this the correct balance of risks? Rocuronium removes the safety net that suxamethonium has of potentially wearing off, should intubation be difficult or impossible, and what is the evidence that suxamethonium causes problems in open eye injury? It is true that suxamethonium causes an increase in intraocular pressure (IOP) of 10 mm Hg,[3] but not using suxamethonium does not imply that increases in IOP are avoided as laryngoscopy alone may cause an increase of 10–15 mm Hg[4 5] and coughing can lead to an increase in IOP of 40 mm Hg.[6] Blinking increases IOP by 5 mm Hg[7] and forceful eyelid closure may cause an increase of up to 70 mm Hg,[8] events likely to have occurred in any person who has suffered a severe eye injury.

In addition, as long ago as 1957[9] thiopentone was shown to abolish the increase in IOP associated with suxamethonium, and Edmondson and colleagues[10] demonstrated in 1988 that there were no significant increases in IOP compared with baseline values when suxamethonium and thiopentone were used as part of a rapid sequence induction and intubation.

More recently, and more significantly, Moreno, Kloess and Carlson[11] using an anterior and posterior trauma model in the cat eye found that there were no cases of vitreous extrusion in 38 separate administrations of suxamethonium. From this they concluded that suxamethonium, when indicated, should be considered in patients with suspected or known open globes.

Have there been cases of vitreous extrusion after suxamethonium reported in the literature? Very few can be found. In 1957 Lincoff, Breinin and DeVoe[9] reported several cases (by personal communication) of prompt expulsion of vitreous when suxamethonium was used to try and forestall impending vitreous extrusion; an unfair situation in which to put all the blame on suxamethonium. The only other report of expulsion of intraocular contents after suxamethonium that I could find was a letter by Rich and colleagues in 1986,[12] but no anaesthetic details were given. This contrasts sharply with the combined 900 cases of penetrating eye injury reported by Libonati, Leahy and Ellison[13] and Donlon[14] where the use of suxamethonium caused no additional damage to the eye.

In conclusion, until we have a non-depolarizing neuromuscular blocking agent with the same potency and short duration of action as suxamethonium, it will always have a place in the balance of risks for a patient with an open eye injury.

BOOK REVIEWS

Handbook of Critical Care, 2nd Edn. R. R. KIRBY, R. W. TAYLOR AND J. M. CIVETTA (editors). Published by Lippincott-Raven, Philadelphia. Pp. 940; indexed; illustrated.

This is the second edition of this manual of critical care. In essence it contains the reference material from the third edition of the textbook *Critical Care* by the same editors, without the background scientific material.

There is a huge amount of information in this book, but extensive use of subheadings, lists, diagrams, highlighted text and panels make it easy to find the relevant information quickly.

The book is divided loosely into two halves covering surgical and medical intensive care, and then subdivided into 11 major sections and a total of 65 chapters. Each chapter contains details of diagnosis and treatment, expected laboratory findings and clinical information, and also a considerable amount on related practical procedures. Many of the descriptions of procedures are accompanied by excellent line drawings, and in general the illustrations in the book are excellent. A set of appendices give useful tables and data.

This is, of course, an American book and so contains American drug names and non-SI units, and the resuscitation guidelines follow the American Heart Association algorithms. However, this should not pose a practical problem in understanding or using the information in the book. A chapter summarizing the treatment of poisons would have been helpful, although most of the information is available elsewhere in the book.

In summary, this is an excellent pocket size handbook containing a wealth of information on all aspects of intensive care. It is the type of book which should be available in the intensive care unit to help all grades of practitioners with day to day problems. I would urge you to buy one for yourself.

J. D. Young

Practical Obstetric Anesthesia. D. M. DEWAN AND D. D. HOOD (editors). Published by WB Saunders, Philadelphia. Pp. 385; indexed; illustrated. Price £39.00.

Writing a practical guide to an area of practice as controversial as obstetric anaesthesia must be a daunting undertaking. This book is aimed at "obstetric anaesthesia care providers", and covers both the relevant background and actual delivery of care. Therefore, it fits into the gap between purely practical guides and Chestnut's comprehensive *Obstetric Anesthesia, Principles and Practice*.

The first chapters cover background material, including a review of anaesthetic-related maternal morbidity and mortality, relevant physiology and pharmacology, and a discussion of fetal and maternal monitoring. The emphasis throughout is on the practical relevance of the information presented.

Next are sections on analgesia for labour and anaesthesia for Caesarean section. There is much that is controversial in this field, but the authors present consistently safe and effective practice and cover most of the relevant techniques. There is much good advice, with emphasis on early resiting of extradurals rather than struggling with poor blocks. The UK reader, however, will search in vain for any reference to the use of 0.5% hyperbaric bupivacaine for spinal anaesthesia, because of the North American emphasis of the book.

The later chapters are a series of well chosen topics related to the "complicated" obstetric patient. These chapters are mostly excellent, and include relevant background and practical advice on management throughout. Chapters on anaesthesia for non-birth-related surgery in pregnancy, postoperative analgesia, resuscitation and medico-legal aspects conclude the book.

The multi-author text has been well edited, and there is good cohesion between chapters with minimal repetition. The list of "10 practical points" at the end of each chapter works surprisingly well. Each chapter is followed by a list of references, which are generally useful and up to date. The standard of presentation is excellent, with clear layout and good print. The many useful tables and diagrams make it easy to find information.

It is written entirely by North American practitioners, and therefore to the UK reader there are the usual unfamiliar drug names, and much information on drugs which are not used widely in the UK (e.g. 2-chloroprocaine, amylocaine and sufentanil). Perhaps more important are the many real differences in practice between the two cultures. For example, although the use of Entonox is acknowledged as still being common in the UK, the use of inhalation analgesia in labour is dismissed as "impractical in many new units", and in another chapter is dismissed altogether because of its "potential to ... obtund airway reflexes". Similarly, TENS is omitted from the chapter on analgesia in labour, although hypnosis and acupuncture are mentioned. (Interestingly both TENS and Entonox are mentioned as possibilities for the woman with AIDS in labour.) The North American experience with bupivacaine is emphasized throughout, with constant references to its increased toxicity in labour.

Despite this, there is much that is good in this book. I would recommend that the delivery suite keep a copy. It will be well used.

P. Rasey

Cambridge Textbook of Accident and Emergency Medicine. D. SKINNER, A. SWANN, R. PEYTON AND C. ROBERTS (editors). Published by Cambridge University Press, Cambridge. Pp. 1271; indexed; illustrated. Price £120.00.

The book has 1271 pages, is indexed and, although text-based, has many appropriate illustrations where required.

Accident and emergency is a new specialty, in the past borrowing information from other specialties where required. The only substantive texts have been American. This truly excellent book is the first of real stature to appear in accident and emergency and is extremely welcome.

It is notable that there are many authors, both from accident and emergency, and other specialties and, indeed, from other countries, showing the diverse nature of the specialty from major trauma to dermatology, pre-hospital to non-accidental injury, airway to envenomation.

The book is divided into three sections: general principles, trauma, medical, surgical and obstetric emergencies. The trauma section follows very closely ATLS principles and priorities, other sections dealing with children follow PALS and cardiac sections follow ALS principles and philosophy. Indeed, even the structure of the chapters (introduction, dialogue and closure) follows the educational principles of these three major training courses. The last section is set out in a problem-orientated, rather than diagnosis-orientated way, which is the system used in accident and emergency.

I feel this is a must for all trainees in accident and emergency, particularly of registrar and above standard. I think it ought to be available in all accident and emergency departments as a reference for SHOs and other visiting specialist junior doctors.

It would also form a good reference for many other specialties in training, particularly paediatric, anaesthetic and surgical, as it provides up to date techniques and management protocols which are sometimes not covered fully in other texts. The reference sections are very topical.

Although accident and emergency is a small specialty, it touches many others in hospitals, in addition to pre-hospital practice; this textbook forms an excellent reference for those involved and is highly recommended.

EDITORIAL

Resuscitation

In 1942 Geoffrey Organe,[1] later Professor Sir Geoffrey Organe, addressed the Section of Anaesthetics of the Royal Society of Medicine on "resuscitation". His presentation focused on cardiac arrests occurring in association with anaesthesia and surgery and his assessment of the attempts at resuscitation. In 1942 monitoring of cardiac rhythm, oxygenation and ventilation, which we take for granted today, was not available; electrical defibrillation and external cardiac massage had not been considered; i.v. fluid was considered hazardous in most cases, but blood transfusion was recognized as treatment for overt haemorrhage. Adrenaline (*epinephrine* see below) was used, but was thought on occasion to cause ventricular fibrillation. Organe showed remarkable foresight in his suggested routine for resuscitation. This included clearing of the airway and artificial ventilation with oxygen, the pros and cons of tracheal intubation, direct stimulation of the heart by transthoracic puncture of the right atrium (although no mention is made of injecting drugs by this route), direct cardiac massage by laparotomy and, if necessary, opening the chest through the diaphragm, and finally the use of drugs. Injection of adrenaline transthoracically into the left ventricle is advocated as "a measure of desperation" and the use of procaine if the "surgeon's hand confirms ventricular fibrillation" during cardiac massage. Lignocaine (*lidocaine* see below) had yet to be developed in 1942. Organe concluded "if a satisfactory circulation is not established within four to five minutes, permanent damage to the brain is likely to occur, leading to death at a later period". Some 55 years on the urgency of restoring the circulation accompanied by adequate ventilation is still centre stage.

This year has seen major changes in resuscitation concepts and it is very appropriate that the *British Journal of Anaesthesia* should take "resuscitation" as a title for a postgraduate issue. Anaesthetists have been one of the driving forces in promoting a rational approach to resuscitation, starting with the confined area of cardiac arrest in the operating theatre, to the current trend of teaching basic and advanced life support to all health professionals, involvement in intensive care medicine and trauma, in addition to special situations. The reviews in this issue cover all of these aspects and provide the reader with a current view. We should not forget the major contributions of other specialties to resuscitation and its international nature. This is illustrated by our authors in this issue and the membership of organizations such as the Resuscitation Council of the United Kingdom, the European Resuscitation Council (ERC) and the International Liaison Committee on Resuscitation (ILCOR). These groups[2] are currently upgrading their guidelines, all of which are referred to in this issue.

Resuscitation is not performed by most anaesthetists on a regular basis. However, there is a perception that we are the lead specialty in this area. Part 3 of the FRCA contained as part of its examination process a station on resuscitation in the objectively structured clinical examination (OSCE). This required candidates to demonstrate, using a manikin, basic life support and pattern recognition of cardiac arrythmias. Despite wide publicity, it was clear that some candidates were unaware of any of the algorithms displayed on the walls of most hospitals. The OSCE has now been moved to the new Primary FRCA and it would not be betraying any secret to point out that the resuscitation station is still there. *BJA* is sometimes accused of not being clinical enough in its content. This issue gets to the heart of a part of clinical practice which all anaesthetists, regardless of their interests, be they trainees or consultants, should be confident that they could do correctly if required. Do you know where the defibrillator and resuscitation drugs are in your operating theatres, intensive care unit and other acute care settings? Do you know how to use the defibrillator? In a recent coroner's court in the UK some 15 health professionals (including some anaesthetists) had to own up to the fact that none knew how to operate the defibrillator provided for them at a cardiac arrest.

Many of the reviews show protocols to be followed in the various aspects of resuscitation. These have been devised by consensus and represent best thinking at the time they are published. None is written in stone and the various resuscitation councils would be the first to acknowledge that they will be subject to change. Randomized clinical studies of resuscitation protocols have obvious ethical and practical difficulties. Nevertheless, uniform reporting in resuscitation is part of the way forward and one review details current thinking in this area. Some of our senior colleagues do not find protocol compliance easy; they believe that their personal experience outweighs any protocol. However, a recent article[3] in this journal showed that when faced with a simulated critical incident, anaesthetists' recollections were at variance with what actually occurred. Therefore, it might be better for all of us to contribute to the consensus rather than to a nihilistic approach. The latter is much easier and sometimes makes entertaining reading in non-peer reviewed publications, but in the real clinical world it is hard to defend a colleague who knows nothing of protocols and has clearly not done anything else based "on their experience" to resuscitate a patient.

Resuscitation by its nature deals with emergencies and often involves staff not always familiar with all aspects of a patient's condition and treatment. We are now quite good in many situations at immediate restoration of the circulation, as advocated by Organe, but of course the patient may not eventually survive. Should we have started on resuscitation in the first place without all the relevant information? The review on ethical aspects of resuscitation explores this difficult area. It is not now fashionable to assume that doctors take the Hippocratic oath on qualification, but the principle expressed in "I will use treatment to help the sick according to my ability and judgement, but I will never use it to injure or wrong them" is surely one to which all doctors subscribe.

Finally, what's in a name? Around the world the names adrenaline, noradrenaline and lignocaine often follow what might be called their original nomenclature as written here; but increasingly as drug manufacture has become international, epinephrine for adrenaline, norepinephrine for noradrenaline and lidocaine for lignocaine have become more common. As this postgraduate issue illustrates, much of resuscitation is protocol driven to accommodate the wide range of health personnel involved. Obviously any confusion over the names of key resuscitation drugs is undesirable. The solution rests with an attempted international agreement between all national authorities that epinephrine, norepinephrine and lidocaine should be the recommended names and that they would be mandatory for all publications after April 1998. The reviews in this issue of the journal were recruited before this agreement was sought and the current journal style is for the original names of the drugs. In the UK the authority on names of drugs is the Medicines Control Agency. To date it has yet to agree to the changes. *BJA* will, of course, abide by any decision of the Medicines Control Agency and readers will see a change of style, if necessary, in future issues.

Basic life support

A. J. HANDLEY

This review introduces the new guidelines for basic life support for use in the UK, approved by the Resuscitation Council (UK), and based on the work of the International Liaison Committee on Resuscitation. Some of the background reasoning behind the development of these guidelines is discussed.

Basic life support

The term basic life support (BLS) refers to maintaining an airway and supporting breathing and the circulation. It comprises the following elements: initial assessment, airway maintenance, expired air ventilation (rescue breathing; mouth-to-mouth ventilation) and chest compression. When all are combined the term cardiopulmonary resuscitation (CPR) is used. BLS implies that no equipment is used; when a simple airway or face mask for mouth-to-mask resuscitation is used, this is defined as "basic life support with airway adjunct".

The purpose of BLS is to maintain adequate ventilation and circulation until a means can be obtained to reverse the underlying cause of the arrest. It is therefore a "holding operation", although on occasion, particularly when the primary pathology is respiratory failure, it may itself reverse the cause and allow full recovery.

History

The earliest reference to mouth-to-mouth ventilation is considered to be in the Bible, when God created Adam,[10] and when the prophet Elisha revived an apparently dead child.[11] An early medical report of success was reported by Tossach in 1744.[61] After this report, however, there was no further progress with the technique, and attention was turned towards manual methods such as those described by Silvester,[67] Schafer[64] and Holger Nielsen.[33] It is possible that the prudery of the Victorian era prevented acceptance of any method which involved lip contact, but it was not until the 1950s that mouth-to-mouth ventilation was rediscovered and became accepted universally as the method of choice. The inefficiency of the manual methods has led to them being abandoned.[59]

Closed chest cardiac massage was first described in 1878 by Boehm[61] and used successfully in a few cases of cardiac arrest over the next 10 years. After that, however, open chest massage became the standard management for cardiac arrest until 1960, when the classic article on closed chest massage by Kouwenhoven, Jude and Knickerbocker was published.[44] As this coincided with the rebirth of mouth-to-mouth ventilation, 1960 could be considered the year in which modern cardiopulmonary resuscitation was born.

Does BLS work?

Approximately 70% of all cases of cardiac arrest occur out of hospital, often in the victim's home.[27] Early intervention by a bystander—calling for the emergency services and initiating CPR—can materially improve eventual outcome.[18] The sooner that BLS can be instituted the better is the outcome.[21] The concept of the "chain of survival" (see fig. 1) emphasizes that optimum results can be achieved only with the four elements of: early access, early CPR, early defibrillation and early advanced cardiac life support.[19] Most cases of survival from cardiac arrest occur when the victim is in ventricular fibrillation, and the effect of CPR is to prevent this rhythm from degenerating into asystole,[74] the prognosis for which is poor.[77] The provision of a defibrillator at the earliest possible opportunity is of prime importance. The longer the delay before this can be achieved, the more important is the provision of CPR.[12] The opposite is also the case; where the emergency back-up is so well advanced that a defibrillator can be provided on scene within 3–4 min, initial CPR is of little benefit.[71]

For a witnessed, out-of-hospital cardiac arrest when the victim is in ventricular fibrillation, a survival rate to leaving hospital of approximately 30% should be possible.[23] Recent reports show that this can be achieved in Europe.[25]

If cardiac arrest occurs in hospital, the outcome depends on the underlying condition of the patient[41]: approximately 15% may be expected to

The chain of survival
Early access to emergency services
Early BLS to buy time
Early defibrillation to reverse VF
Early advanced care to stabilize

Figure 1 The concept of "chain of survival". The concept emphasizes that optimum results can be achieved only with the four elements of: early access, early CPR, early defibrillation and early advanced cardiac life support. BLS=Basic life support, VF=ventricular fibrillation.

leave hospital alive.[73] For these patients, CPR may play a much lesser role compared with defibrillation and advanced life support.[41]

BLS guidelines

Since 1975 the American Heart Association has periodically issued standards and guidelines for the performance of resuscitation including BLS.[24,68,69,70] These guidelines have been followed by many organizations throughout the world, but there have also been numerous variations. In 1992 the European Resuscitation Council issued guidelines particularly appropriate to the emergency care facilities available within Europe.[5] The Resuscitation Council (UK) adopted these guidelines which then became the standard for this country.[26]

In 1993 the Basic Life Support Group of the International Liaison Committee on Resuscitation (ILCOR) was formed to review existing BLS guidelines from around the world, and to produce a document, or "advisory statement", that could be used as a resource by organizations wishing to develop their own guidelines. The group consists of representatives from resuscitation councils throughout the world, including the American Heart Association, Australian Resuscitation Council, European Resuscitation Council, Heart and Stroke Foundation of Canada, and Resuscitation Council of Southern Africa. An "advisory statement" on BLS (and on advanced life support and paediatric life support) has now been produced.[37] This advisory statement has been adopted, with minor modifications, by the Resuscitation Council (UK) and is presented below.

Even though the value of early, bystander CPR is universally recognized and public CPR programmes have been in existence for approximately 30 yr, most communities still fail to train a sufficiently high proportion of the public to perform basic life support.[27] Paradoxically, in some high-risk populations, the likelihood of bystander CPR being performed is particularly poor.[8,23]

The special challenge when producing guidelines for BLS is to make them equally applicable for use by members of the general public and by health care professionals.

The BLS group of ILCOR set itself four objectives—the advisory statements had to: (a) embrace modern scientific opinion; (b) be as simple as possible to aid skill retention; (c) be the best advice available whatever the cause or nature of the cardiopulmonary arrest; (d) be acceptable to all countries and organizations

Inevitably, objectives (c) and (d) required compromise decisions. Some variations had to be incorporated to allow for the different causes of collapse, particularly the difference between primary respiratory and primary cardiac arrest. It was also accepted that differences in the level of national and local emergency medical services would dictate the optimum point in the resuscitation attempt when the lone rescuer should leave the victim to go to obtain help.

What should be taught?

What the public is taught must be based on the most up-to-date available scientific evidence. BLS skills have to be taught, learnt and remembered, yet are often only used for the first time months or years later. It is well recognized that skill decay is rapid, even among professionals.[9,15,54] This may be caused partly by poor standards of teaching,[42] but partly also by the highly complex nature of the psychomotor skills involved. Within 4 months of being trained, 50% of first aiders were unable to perform adequate CPR on a manikin[35]; 6 months after a public course in BLS, only approximately 7% of those attending were deemed able to perform safe and effective CPR.[51]

The psychomotor skills required for BLS are particularly susceptible to rapid decay. Almost 50 separate skills are needed to perform the current sequence of CPR, which is partly the reason why learning and retention are difficult.[30] Clearly it would be possible to simplify BLS techniques for the lay person to no more than "pump and blow". In contrast, far more complicated procedures than those currently published could be developed by the addition of more comprehensive assessment of the victim, and different emphasis of management depending on the aetiology of the respiratory or cardiac arrest. It is not known how "simple" training could be made in order to aid skill retention, while still maintaining clinical effectiveness.

There is uncertainty within the literature regarding how "good" CPR has to be in order to save a life.[45] Do victims who receive perfectly performed compressions and rescue breathing (so called "good CPR") fare better than victims who receive less effective CPR? A definitive answer is still awaited, but the clear conclusion from many studies is that the lowest survival rates occur when there is no attempt at CPR.[12] Any CPR is better than no CPR. Therefore, a simple, basic approach that can be taught effectively to the largest number of people should help to increase the pool of individuals willing to attempt BLS.

The following *sequence of actions* is aimed primarily at the single lay rescuer dealing with an adult victim. Health care providers and emergency personnel are likely to possess extended resuscitation skills, and the situations in which they may be called upon to use these skills often require more complicated BLS guidelines. The underlying principles, however, remain the same.

These guidelines are intended for the resuscitation of adults, but the principles can be applied effectively to infants and children. Guidelines specific to infants and children are discussed elsewhere in this issue of the journal. In the following descriptions, the masculine includes the feminine.

Sequence of actions (fig. 2)

1. *Ensure safety of rescuer and victim.*
2. *Check the victim and see if he responds.*
- Gently shake his shoulders and ask loudly: "Are you all right?"

3A. *If he responds by answering or moving.*
- Leave him in the position in which you find him (provided he is not in further danger), check his condition and get help if needed.
- Reassess him regularly

3B. *If he does not respond.*
- Shout for help.
- Open his airway by tilting his head and lifting his chin: if possible with the victim in the position in which you find him, place your hand on his forehead and gently tilt his head back keeping your thumb and index finger free to close his nose if rescue breathing is required; at the same time, with your fingertip(s) under the point of the victim's chin, lift the chin to open the airway; if you have any difficulty, turn the victim onto his back and then open the airway as described. Avoid head tilt if trauma to the neck is suspected.

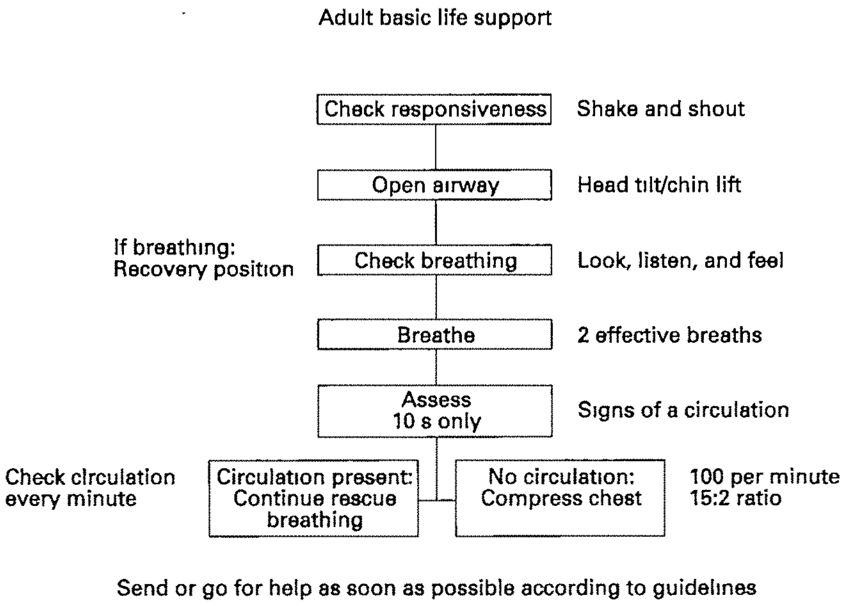
4. *Keeping the airway open, look, listen and feel for breathing (more than an occasional gasp).*

Look for chest movements; listen at the victim's mouth for breath sounds; feel for air on your cheek.
- Look, listen and feel for *up to 10 s* before deciding that breathing is absent.

5A. *If he is breathing (other than an occasional gasp).*
- Turn him into the recovery position.
- Check for continued breathing.

5B. *If he is not breathing.*
- Send someone for help or, if you are on your own, leave the victim and go for help (see below); return and start rescue breathing as below.
- Turn the victim onto his back if he is not already in this position.
- Remove any visible obstruction from the victim's mouth, including dislodged dentures, but leave well fitting dentures in place.
- Give two *effective* rescue breaths, each of which makes the chest rise and fall: ensure head tilt and chin lift; pinch the soft part of his nose closed with the index finger and thumb of your hand on his forehead; open his mouth a little, but maintain chin lift; take a breath and place your lips around his mouth, making sure that you have a good seal; blow steadily into his mouth for approximately 1.5–2 s watching for his chest to rise; maintaining head tilt and chin lift, take your mouth away from the victim and watch for his chest to fall as air comes out.
- Take another breath and repeat the sequence as above to give two effective rescue breaths in all.
- If you have difficulty achieving an effective breath: re-check the victim's mouth and remove any obstruction; re-check that there is adequate head tilt and chin lift; make up to five attempts in all to achieve two effective breaths; even if unsuccessful, move on to assessment of circulation.

6. *Assess the victim for signs of a circulation.*
- Look for any movement, including swallowing or breathing (more than an occasional gasp).
- Check the carotid pulse.
- Take no more than 10 s to do this.



Adult basic life support
Check responsiveness
Shake and shout
Open airway
Head tilt/chin lift
If breathing: Recovery position
Check breathing
Look, listen, and feel
Breathe
2 effective breaths
Assess 10 s only
Signs of a circulation
Check circulation every minute
Circulation present: Continue rescue breathing
No circulation: Compress chest
100 per minute 15:2 ratio
Send or go for help as soon as possible according to guidelines

Figure 2 Algorithm for adult basic life support. The sequence of actions is aimed primarily at the single lay rescuer dealing with an adult victim.

7A. *If you are confident that you can detect signs of a circulation within 10 s.*

- Continue rescue breathing, if necessary, until the victim starts breathing on his own.
- Approximately every minute re-check for signs of a circulation; take no more than 10 s each time.
- If the victim starts to breathe on his own but remains unconscious, turn him into the recovery position. Check his condition and be ready to turn him onto his back and re-start rescue breathing if he stops breathing.

7B. *If there are no signs of a circulation, or you are at all unsure.*

- Start chest compression: locate the lower half of the sternum and place the heel of one hand there, with the other hand on top of the first; interlock the fingers of both hands and lift them to ensure that pressure is not applied over the victim's ribs. Do not apply any pressure over the upper abdomen or bottom tip of the sternum; position yourself vertically above the victim's chest and, with your arms straight, press down on the sternum to depress it between 4–5 cm (1.5–2 in); release the pressure, then repeat at a rate of approximately 100 times a minute (a little less than two compressions a second). Compression and release should take an equal amount of time.
- Combine rescue breathing and compression: after 15 compressions tilt the head, lift the chin and give two effective breaths; return your hands immediately to the correct position on the sternum and give another 15 compressions, continuing compressions and breaths in a ratio of 15:2.

8. *Continue resuscitation until:*

The victim shows signs of life, qualified help arrives or you become exhausted.

Readers will note a number of changes between this sequence of actions and the BLS guidelines adopted by the Resuscitation Council (UK) in 1992.[39] Many of the changes are minor and represent consensus agreement. However, there are a number of topics where an explanation of how the final decisions were reached is of value.

Volume and rate of ventilation

Rescue breathing has been a well accepted technique of airway management in BLS since the early 1960s.[60] The volume of air required for each inflation has been quoted as 800–1200 ml, with each breath taking 1–1.5 s.[24]

Artificial ventilation without airway protection (such as tracheal intubation) carries a high risk of gastric inflation, regurgitation and pulmonary aspiration.[6] The risk of gastric inflation depends on: (a) proximal airway pressure, which is determined by tidal volume and inflation rate; (b) alignment of the head and neck, and degree of patency of the airway; and (c) opening pressure of the lower oesophageal sphincter (approximately 20 cm H_2O).[57]

It has been shown recently that a tidal volume of 400–500 ml is sufficient to provide adequate ventilation in adult BLS because carbon dioxide delivery during cardiac arrest is very low.[7 34] Although this value is lower than that recommended previously, it is consistent with the accepted teaching that tidal volume should be that which causes the chest to rise as in normal spontaneous breathing.

During combined rescue breathing and chest compression, the rate of ventilation is dependent on both the ventilation volume and compression rate. An inflation time of 1.5–2 s diminishes the risk of exceeding the oesophageal opening pressure and results in an inflation/exhalation cycle of approximately 3 s. A chest compression rate of approximately 100 per minute is recommended (see below). It therefore takes 9 s to perform 15 cardiac compressions. Allowing 6 s for the two rescue breaths, single rescuer CPR should result in about 8 breaths and 60 chest compressions per minute.[6]

Circulatory assessment

The single most important sign of cardiac arrest in an unconscious, non-breathing adult has always been the absence of a carotid pulse. Current teaching is that pulselessness should lead to the initiation of chest compression. The time allowed to feel for the pulse differs between resuscitation councils[5 24 43] but none recommends more than 10 s for a normothermic victim, as time is critical when starting CPR.

Should the "carotid pulse check" still be taught as the sole criterion for the initiation of chest compression? Is the carotid pulse check in fact difficult, particularly for lay persons?

Recent studies have strongly suggested that the time needed to diagnose with confidence the presence or absence of a carotid pulse is far greater than the 5–10 s normally recommended, with times in excess of 30 s being needed to achieve a diagnostic accuracy of 95%.[2 28 29 47] Even with prolonged palpation, 45% of carotid pulses may be pronounced absent when in fact present.[20] It should also be borne in mind that most of the studies were undertaken using normotensive volunteers, a situation far different from finding a collapsed, cyanosed victim in the street who is likely to be hypotensive, vasoconstricted or worse.

Many ambulance services offer CPR instruction over the telephone to callers reporting victims who have collapsed. The criteria for advising CPR are normally a combination of unresponsiveness and lack of breathing.[48] It is not usual practice for the dispatcher to ask for a carotid pulse check before advising chest compression, mainly because of the perceived difficulty in describing the technique over the telephone.

As a result of these considerations the BLS group of ILCOR has recommended that the carotid pulse check should be "de-emphasized" and that other criteria should be used to determine the need for chest compression in an unresponsive, apnoeic adult patient. It was decided to use the expression: "Look for signs of a circulation", to include looking for movement and checking the carotid pulse. The rescuer should limit the time taken for this check to no more than 10 s. Therefore, absence of any obvious signs of life, not necessarily absence of the carotid pulse, should be sufficient indication to initiate chest compression.

It should be emphasized that this departure from current teaching is aimed, at least for now, only at the lay rescuer; checking for a pulse remains an important part of advanced life support and the algorithm for use of automatic external defibrillators.

Rate of chest compression

The original term "cardiac massage" and its successor "external cardiac compression" reflect the initial theory as to how chest compressions achieve an artificial circulation—namely, by squeezing the heart. This "heart pump theory"[44] was criticized in the mid-1970s, first because echocardiography demonstrated that the cardiac valves become incompetent during resuscitation[55 76] and, second, because coughing alone was shown to produce a life-sustaining circulation.[17] The alternative "thoracic pump" theory[58] proposes that chest compression, by increasing intrathoracic pressure, propels blood out of the thorax; forward flow occurs because veins at the thoracic inlet collapse while the arteries remain patent.

An extension of the controversy raised by these conflicting theories is the argument as to whether or not the rate of chest compression during resuscitation should be fast or slow. In practice, compression rates of 40–120 per minute have successfully resuscitated patients in cardiac arrest; changes in national and international recommendations reflect mainly changes in consensus opinion. It is important, however, to recognize that even when performed optimally, chest compressions do not achieve more than 30% of the normal cerebral perfusion.[61]

Because a more rapid rate of chest compression is required in infants and children, and because simplification of the guidelines is seen as an important objective, a universal compression rate of 100 per minute (expressed for the lay person as: "a little slower than two a second") seems an admirable compromise.

What is important, however, is that the compression and relaxation phases should each occupy about half the compression: relaxation cycle in order to maximize blood flow.[75] In practice, this is difficult to achieve.[38]

Call first—call fast

The first link in the "chain of survival"[19] is to gain access to the emergency medical services. Advice as to the optimum time during a resuscitation attempt at which to leave the victim to go for help depends on several factors: whether the rescuer is alone; whether the victim has a primary respiratory or primary cardiac arrest; the distance to the nearest point of aid (for example a telephone); and the facilities offered by the emergency services.

The importance of early defibrillation in the treatment of sudden cardiac death is now accepted, and major initiatives are moving forward to deliver a defibrillator and the first shock at the earliest possible moment.[22] The 1992 AHA guidelines[24] emphasized that the rescuer should, if no other help is available, leave an adult victim immediately after establishing unresponsiveness in order to call an ambulance or emergency medical service ("phone first"). The ERC guidelines[5] advise that a shout for assistance should be made as soon as the victim is found to be unconscious, but that the loan rescuer should not leave to go for help until cardiac arrest is diagnosed by means of a pulse check ("phone fast"). Both the AHA and ERC guidelines seek to ensure that a defibrillator reaches the victim at the earliest appropriate opportunity. Both agree that if the victim is a child, the rescuer should provide rescue support (ventilatory or circulatory or both) for about 1 min before leaving the victim and calling the rescue team.[50]

In children the aetiology of cardiopulmonary arrest is different from that of the adult.[40] Respiratory arrest is far more common than cardiac arrest which, if it occurs, is usually secondary to respiratory arrest. The outcome of attempts at resuscitation from cardiac arrest in children is dismal at best, with a high chance of poor neurological status afterwards.[65] Survival after cardiopulmonary arrest in children is dependent mainly on the immediate provision of effective rescue breathing,[31] hence the recommendation of 1 min rescue support before leaving and phoning for help.

Although the current (and proposed) guidelines define a child as up to the age of an adult (presumed 18 yr), there is evidence that the increased frequency of primary respiratory arrest persists until approximately 30 yr of age.[1 49] A difficulty that would be encountered using this age as the cut-off between going for help at once or undertaking initial basic life support, would be finding a way of describing (particularly to the lay person) how to determine the age of the collapsed adult victim. As so often is the case, a "best compromise" wins the day.

In the USA a "call first" policy exists, with full emergency service dispatch taking place if a victim is reported to be unresponsive. The ambulance service in the UK is moving towards the US model of priority-based dispatch, and when an emergency call is received, the caller is now usually asked whether the victim is conscious or unconscious, breathing or not breathing. Unlike the US system, however, a top priority dispatch takes place only if the victim is unconscious and not breathing. As already discussed, the presence or absence of a pulse is not a factor in determining priority further. Because of the different policies of the two countries, the Resuscitation Council (UK) advises that the time for the lone rescuer to leave the victim to go for help should normally be immediately after establishing absence of breathing.

There is a further argument against giving two breaths before a rescuer leaves the victim. It has been shown that in some communities there is a reluctance to perform rescue breathing, or a delay in starting ventilation, on a stranger because of concern over disease transmission, particularly the fear of contracting HIV.[14 53] By advising that a call to the ambulance service should be made as soon as the absence of breathing has been established, help can be found with the minimum of delay.

For of all these reasons, the Resuscitation Council (UK) has endorsed the following advice:

When to get help

It is vital for rescuers to get help as quickly as possible.

- When more than one rescuer is available, one should start resuscitation while another rescuer goes for help.
- A lone rescuer has to decide whether to start resuscitation or to go for help first. In these circumstances, if the likely cause of unconsciousness is trauma (injury), drowning *or* if the victim is an infant or a child, the rescuer should perform resuscitation for *approximately 1 min* before going for help.

If the victim is an *adult*, and the cause of unconsciousness is *NOT* trauma or drowning, the rescuer should assume that the victim has a heart problem and go for help immediately after establishing unresponsiveness and the absence of breathing

Recovery position

The airway of an unconscious victim who is breathing spontaneously is at risk of obstruction by the tongue and from inhalation of mucus and vomit. Placing the victim on the side helps to prevent these problems, and allows fluid to drain easily from the mouth. This lateral, coma, side or recovery position, has been advocated in anaesthesia for more than 100 yr[13] and is still standard practice today. It is surprising, therefore, that its introduction into first aid practice was only within the past 50 yr.[63] Perhaps even more surprising is that in 1992 there was no mention of a recovery position in the AHA guidelines.[24]

Some compromise is needed when positioning the victim; a true lateral posture tends to be unstable, involves excessive lateral flexion of the cervical spine and results in less free drainage from the mouth. A near-prone position, on the other hand, can result in under ventilation because of splinting of the diaphragm and reduction in pulmonary and thoracic compliance.[62]

Potential injury to the victim has also to be considered.[3] There have been several recent reports of interference with upper limb blood flow in association with the recovery position advocated by the European Resuscitation Council.[32 36] This involves the lowermost arm being brought into a ventral position with the uppermost arm crossing it and producing a pressure effect on the blood vessels and, possibly, the nerve supply. Placing the lowermost arm in a dorsal position may not necessarily be the answer, as this involves movement that could, at least theoretically, injury the shoulder joint. However, it is the compromise chosen by the Resuscitation Council (UK) for its 1997 guidelines.

There is inadequate published evidence for definite conclusions but the recognition of the potential for harm and benefit from placing the victim on the side must be remembered.

Many different versions of the recovery position exist, each with its own advocates. The BLS group of ILCOR concluded that it was unable to recommend one specific position, but instead agreed on six principles that should be followed when managing the unconscious, spontaneously breathing victim:

1. The victim should be in as near a true lateral position as possible with the head dependent to allow free drainage of fluid.
2. The position should be stable.
3. Any pressure on the chest that impairs breathing should be avoided.
4. It should be possible to turn the victim onto the side and return to the back easily and safely, having particular regard to the possibility of cervical spine injury.
5. Good observation of, and access to, the airway should be possible.
6. The position itself should not give rise to any injury to the victim.

The future

If one adheres strictly to the definition of basic life support as the maintenance of an airway and support of breathing and circulation without the use of equipment, there is limited scope for improving the current techniques.

Based on the "thoracic pump" theory of chest compression, the greater the intrathoracic pressure produced, the better should be the forward flow of blood. Experimentally this has been achieved by simultaneous compression and ventilation, but intubation with a cuffed tracheal tube is needed to protect the airway from refluxing gastric contents, and to avoid gastric insufflation.[16] Increasing intra-abdominal pressure by the use of an abdominal "vest" also results in an improvement in blood flow during cardiac arrest, but again requires the use of equipment.[66]

Within the strict definition of basic life support, improvement in aortic arterial pressure has been achieved during cardiac arrest without any extraneous equipment by simultaneous chest and abdominal compression,[4] and by increasing the rate of chest compression to 120 per minute.[72] There has also been a tentative suggestion that a return to open chest CPR might be of benefit in some cases.[56]

It is important, however, to bear in mind that there is no published evidence that any of these techniques produce a significant improvement in the outcome of cardiac arrest in the human victim.

The use of a device (Ambu CardioPump) to produce "active compression–decompression" CPR is currently creating a lot of interest, and a flurry of articles in the resuscitation literature. The principle of this device is based on a case described in 1990 of a human resuscitated with the help of a "plumber's helper", better known in the UK as a plunger used for unblocking sink and WC outflows.[46] A rubber suction cup is used alternately to compress then re-expand the chest, thus improving venous return. The reports are encouraging, but proof of increased survival after cardiac arrest is still awaited.[52] If this is forthcoming, the device may represent an important advance in basic life support, albeit with the use of an adjunct.

For the time being, the way to improve survival, particularly in out-of-hospital cardiac arrest, lies with increased public education in the basic techniques of rescue breathing and chest compression, linked closely to greater awareness of the need to call early for the emergency services and the provision of first responder defibrillation.

Management of the airway and ventilation during resuscitation

D. A. GABBOTT AND P. J. F. BASKETT

The management of the airway and ventilation is a vital component in the resuscitation of patients with respiratory and cardiac arrest.

In recent years considerable emphasis has been placed on the cardiac and vascular elements of resuscitation as the value of early defibrillation has become appreciated as the principal element in producing a return of spontaneous circulation in those with cardiac arrest.[31, 39] Nevertheless, the role of maintaining oxygenation during the resuscitative process is no less important in order to ensure protection of the vital organs from hypoxic damage. In June 1996 the Airway and Ventilation Management Working Group of the European Resuscitation Council published their guidelines for the basic and advanced management of the airway and ventilation during resuscitation.[34, 35] Since then several national resuscitation councils in continental Europe, the UK, Australasia and Southern Africa have adopted these guidelines in principle.

The airway in resuscitation

Airway obstruction may be a prime cause of cardiorespiratory arrest or may occur as a consequence of unconsciousness. Common causes are listed in figure 1. Untreated, the wholly obstructed airway will, within a very short period (generally accepted as 2–5 min except in unusual circumstances, e.g. hypothermia or intoxication with sedative or opioid drugs) cause neurological or other vital systemic damage which may be irreversible or fatal.

BASIC ASSESSMENT

Assessment of the airway is based on a check for unresponsiveness, examining chest movements and feeling for air flow from the mouth and nose. The assessment should be made in the position in which the patient is found, especially if trauma is suspected (see below). If breathing is absent the patient should be turned to the supine position (using manual in-line stabilization of the head and neck if there is a potential cervical spine injury). The head and neck

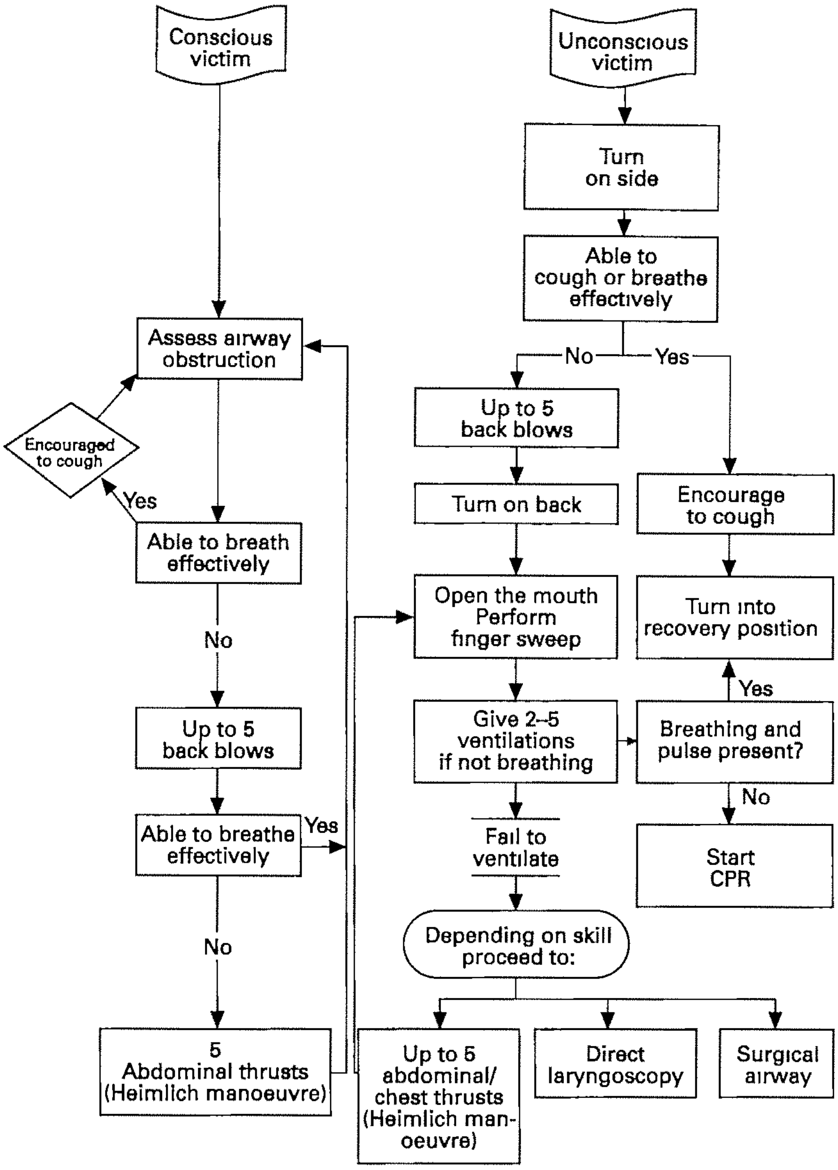
should be aligned in the clear airway position using head and chin lift tilt (omitted if there is a possibility of cervical spine injury), and jaw thrust. Ideally, the head should be placed on a small pillow to achieve the "sniffing the morning air position". When the head and neck are aligned the assessment should be complemented by seeking other signs, such as cyanosis, pallor, excessive salivation, gastric contents or foreign body in the mouth or pharynx, and evidence of head, maxillofacial, neck or chest trauma. Abnormal phonation or breath sounds and wheeze or stridor indicate a particularly obstructed airway. Stridor occurring during inspiration generally indicates obstruction above the larynx, wheeze occurring during expiration usually indicates obstruction below the larynx. A suggested plan for assessment of the airway and breathing is shown in figure 2.

Management of the upper airway obstructed by foreign material (choking)

CAUSES AND SIGNS

In adults the commonest causes are aspiration of



Conscious victim
Assess airway obstruction
Encouraged to cough
Yes
Able to breath effectively
No
Up to 5 back blows
Able to breathe effectively
Yes
No
5 Abdominal thrusts (Heimlich manoeuvre)
Unconscious victim
Turn on side
Able to cough or breathe effectively
No
Yes
Up to 5 back blows
Turn on back
Open the mouth Perform finger sweep
Give 2–5 ventilations if not breathing
Fail to ventilate
Depending on skill proceed to:
Up to 5 abdominal/ chest thrusts (Heimlich manoeuvre)
Direct laryngoscopy
Surgical airway
Encourage to cough
Turn into recovery position
Yes
Breathing and pulse present?
No
Start CPR

Figure 3 Algorithm for the management of upper airway obstruction caused by foreign materical (choking).

gastric contents or blood associated with loss of the protective laryngeal reflexes and choking on large portions of poorly chewed food. In children and the mentally challenged, a large number of other ingested articles may be added to these causes, for example peanuts, marbles, pen tops, beads, etc. Choking is heralded by respiratory distress, stridor, wheezing and coughing. As the obstruction becomes more complete, airflow is reduced, the patient is unable to speak or breathe and cyanosis occurs. Unconsciousness supervenes and death occurs if the obstruction is not relieved immediately. The patient may clutch or point to his or her neck—a universal distress signal for imminent choking.

MANAGEMENT

While there appears to be adequate air movement the patient should be encouraged to cough and be observed closely. Oxygen, if available, should be administered. If air movement is poor or absent and the patient becomes cyanosed, immediate positive action is required. The obstruction may be cleared by head and neck alignment, back blows, abdominal or chest thrusts, lateral positioning or finger sweeps, or by using a laryngoscope with suction, Magill forceps or a Kelly clamp to remove the obstruction under direct vision. As a last resort upper airway obstruction may be bypassed by a surgical airway using cricothyroidotomy or needle jet ventilation provided the appropriate skills and equipment are available.

Back blows

A series of five back blows are applied during expiration with the patient standing, sitting or in the lateral position. Preferably the head should be positioned below the chest to achieve the best gravitational drainage advantage. Children should be placed prone with a head down tilt on the rescuer's thigh or arm. If this fails to clear the obstruction, abdominal thrusts should be used.

Abdominal thrusts (Heimlich manoeuvre)

Abdominal thrusts may be applied with the patient standing, sitting or lying down in the supine position. The supine position is used in unconscious patients and in the very obese or when the rescuer finds it impossible to encircle the abdomen of the victim. Abdominal thrusts may result in damage to the abdominal viscera or gastric regurgitation. The technique is not recommended in infants and small children[33] or in advanced pregnancy.

The guidelines of the American Heart Association[32] do not recommend the application of back blows in adults (although they do in infants and small children[73]) and prefer early application of abdominal thrusts. European, Australasian and Southern African guidelines advocate the application of back blows before abdominal thrusts.

Chest thrusts

Chest thrusts are preferred in children and when abdominal thrusts are contraindicated or ineffective. Rhythmic thrusts are applied with both hands to the anterior aspect of the chest in the same position as used for external chest compressions.

Finger sweeps

Finger sweeps should be used only in the unconscious victim who does not have good reflexes or the ability to bite the rescuer's finger. The patient should be placed in the lateral position. Blind sweeps are not generally recommended in infants and small children because of the risk of deeper impaction of the foreign body at the laryngeal level but sweeps using the little finger to extricate an obvious object under direct vision are acceptable. An algorithm for the management of choking is shown in figure 3.

The recovery position

The recovery position is used in unconscious patients with adequate spontaneous breathing to maintain a patent airway and reduce the possibility of aspiration of gastric contents or foreign material in the mouth or pharynx. Several different recovery positions have been advocated (dependent arm behind or in front of the trunk, uppermost arm extended or flexed to place the hand under the cheek, dependent leg extended or flexed, uppermost leg extended or flexed). It has proved impossible to obtain universal international agreement as to the best position but there is consensus as to the principles involved. These principles include:

- The patient should be in as near a true lateral position as possible with the mouth dependent to allow free drainage of fluid.
- The position should be stable.
- Any pressure on the chest that impairs breathing should be avoided.
- Care should be taken to avoid compromise of the circulation in either arm or peripheral nerve compression in the arms and legs.
- It should be easy to turn the victim into the lateral position and return to the supine position, having particular regard to the possibility of injury to the cervical spine.
- Good observation and access to the airway should be possible.

MANAGEMENT OF THE AIRWAY IN PATIENTS WITH SUSPECTED SPINAL INJURY

Great caution must be taken in aligning the head and neck in any trauma victim requiring resuscitation. In these circumstances the cervical spine must be maintained in a neutral mid-line position unless it is physically difficult to do so or resistance is encountered during any attempt at realignment. Manual in-line stabilization is the technique of choice in any trauma patient, with the head grasped firmly at the mastoid processes and the occiput.[52 58] Traction should be avoided as it may distract the cervical spine and cause more neurological damage.[77] Jaw thrust is the only basic airway opening manoeuvre appropriate for any patient with suspected cervical spine injury. Suction and use of forceps under direct vision using a laryngoscope with the head and neck maintained in the neutral position are the best methods of removing foreign material from the mouth and pharynx but back blows and abdominal or chest thrusts are acceptable only in extreme conditions. The risk of hypoxic damage from airway obstruction in an unconscious breathing victim is likely to outweigh the risk of aggravating cervical spine injury in the vast majority of cases and such patients should be placed in the lateral position using a log rolling technique with a minimum of four attendants. The rescuer controlling the head and neck with manual in-line stabilization should be in command of the rotation procedure. When turned, the lower limb should not be flexed unless a thoracolumbar injury is not suspected. Movement of the arms is not recommended.

Basic management of ventilation

In basic resuscitation the method of choice is expired air ventilation using the mouth-to-mouth, mouth-to-nose, mouth-to-mouth-and-nose (neonates) or the mouth-to-mask method. The mouth-to-mask method has aesthetic advantages and may reduce the possibility of cross infection between patient and rescuer. Some models of mask permit the addition of oxygen if available. The hitherto recommended sequence of ventilations in relation to external chest compressions in patients with cardiac arrest has been 1:5 (using two rescuers) and 2:15 (using a single rescuer).[32] Recently, the European Resuscitation Council has recommended that only the single rescuer method (2:15 sequence) should be taught to lay people using the justification that the second person's priority should be to seek and provide help (especially a defibrillator) and that two lay people may find co-ordination of chest compressions and ventilations difficult unless they have practised together regularly. This teaching is likely to be followed on a global scale by authorities in Australasia, Southern Africa, the United States, Canada, Latin America and the Pacific Rim. While there is consensus regarding the technique of application of expired air ventilation there is debate as to the sequence in relation to chest compressions, inflation flow rate and volume of ventilation.

SEQUENCE OF VENTILATIONS AND CHEST COMPRESSIONS

Early guidelines from the American Heart Association (AHA)[68 69] proposed that four ventilations should be given at the beginning of resuscitation using a "step-on-step" technique of applying each subsequent inflation before exhalation was complete, thus introducing a form of positive end-expiratory pressure (PEEP). The rationale behind this practice was the postulation that alveolar collapse occurred with cardiorespiratory arrest and that application of PEEP would improve the situation. The "step-on-step" technique for the first four breaths was rescinded in the guidelines of 1986[70] in the face of evidence that this method generated high proximal airway pressures[40] and that the lower oesophageal sphincter opening pressures were likely to be reduced.[54 81]

Both of these factors were likely to increase the risk of gastric regurgitation and subsequent pulmonary aspiration. The 1986 AHA standards and guidelines reverted to initial application of two normally spaced breaths followed by a one-rescuer sequence (15 compressions/two ventilations) or a two-rescuer sequence (five compressions/one ventilation).

Clearly the 15:2 or 5:1 sequences which were proposed in the late 1950s were based on a concept of normal cardiorespiratory physiology. However, this state of affairs is unlikely to apply in cardiorespiratory arrest when delivery of carbon dioxide to the lungs is likely to be low, so reducing the emphasis on ventilation frequency and volume. What is paramount, however, in cardiac arrest is oxygenation and there is a need for research to establish the best compromise to provide satisfactory oxygenation and carbon dioxide removal under these conditions.

For the future it may be that the frequency of ventilation can be reduced to a sequence of 1 in 10 or even 1 in 20 interposed with external chest compressions while oxygen is insufflated into the lungs. However, in the absence of new positive scientific evidence the principle of adherence to the present recommendations applies.

VENTILATION FLOW RATES AND VOLUMES

Ventilation through an unprotected airway whether using the expired air technique or a self-inflating bag–valve–mask carries a very high risk of gastric inflation and subsequent pulmonary aspiration. Evidence of aspiration has been found in approximately 28% of failed resuscitations examined by the coroner.[45] Weiler, Heinrichs and Dick[81] reported evidence of gastric inflation in two of 31 anaesthetized patients with an unprotected airway ventilated by experts and recommended that inflation pressures should be limited to 20 cm H_2O. The following factors are relevant in considering the possibility of gastric inflation during resuscitation.

- Alignment of the head and neck.
- Lower oesophageal sphincter opening pressures.
- Proximal airway pressure during inflation.

Optimal alignment of the head and neck has been discussed above. The lower oesophageal sphincter opening pressure has been estimated to be in the region of 20 cm H_2O in live patients.[81] In swine subjected to experimental cardiac arrest the oesophageal sphincter opening pressure decreased from 26 to 4 mm Hg.[54] Although there are no comparable data for humans it is likely that a similar decrease occurs as suggested by the high incidence of regurgitation reported during cardiac arrest.[45]

The proximal airway inflation pressure during intermittent positive pressure ventilation is related to the inflation flow rate and tidal volume.

The recommendations of the AHA stipulate that either a tidal volume sufficient to make the chest rise normally, or 800–1200 ml, should be applied over 1–2 s at a rate of approximately 10 bpm.[32] Clearly these numerical volumes aim to achieve hyperventilation.

Training manikins equipped with auditory and visual signals hitherto have been set to conform to tidal volumes of 800–1200 ml. Analysis of these numerical recommendations, however, reveals several difficulties. To maintain inflation pressures at reasonable values (approximately 20 cm H_2O) a tidal volume of, say, 1000 ml requires at least 2.5 s for inflation and another 1 s for exhalation using a single rescuer. Longer times are needed for patients with reduced compliance. Thus two ventilations last at least 7 s, 15 external chest compressions applied at a rate of 80 per minute last 12 s, and therefore the total time for each sequence is (7+12) 19 s. Just over three sequences are completed in 1 minute (i.e. six breaths and 45–50 chest compressions) and while six breaths per minute may be adequate during cardiac arrest, it is unlikely that 45 chest compressions provide a viable circulation. Similar calculations can be performed for a 1:5 sequence with similar results. In considering the alternative component of the recommendations, clinical observation of the chest, it is important to determine the tidal volume associated with a "normal" breath. Baskett, Nolan and Parr showed in anaesthetized patients that adequate chest movement perceived by nurse and medical observers was produced by tidal volumes of 400–500 ml.[11] Calculating the number of chest compressions and ventilations using a tidal volume of, say, 500 ml with the same inflation rate, each sequence would take 3.5 s (two breaths) plus 12 s (15 compressions) = 15.5 s, resulting in just under four sequences per minute, totalling eight breaths and 60 chest compressions.

In clinical resuscitation practice the tidal volume applied is gauged by the rise and fall of the chest and is likely to be approximately 400–500 ml rather than the 800–1200 ml required in manikin practice. It is likely that many victims have survived using tidal volumes of 400–500 ml during resuscitation and certainly the minute volumes generated are more than adequate to clear carbon dioxide during anaesthesia with a normal cardiac output.

For this reason the European, Australasia and Southern African Resuscitation Councils have recommended a tidal volume of 400–500 ml (5–6 ml kg^{-1}) during resuscitation and that training manikins with visual or auditory signals, or both, should

indicate satisfactory inflation at a tidal volume of 400–600 ml.[35]

Many questions remain in this field and can be answered only by research studies which are not easy in patients undergoing resuscitation. Perhaps even smaller tidal volumes would suffice to eliminate carbon dioxide? Would higher compression rates (100–120 per minute) produce better perfusion of vital organs and improved survival rates? Would simple insufflation of oxygen through a patent airway such as a laryngeal mask or tracheal tube provide adequate oxygenation? Given sufficient inspired oxygen concentrations, do standard chest compressions provide adequate pulmonary ventilation to remove the carbon dioxide that is being delivered to the lungs under these circumstances? Or would active compression and decompression of the chest (ACD CPR) using a device such as the Cardiopump (Ambu) be more effective? Does Vest CPR (Cardiologic Systems) provide adequate pulmonary ventilation? These and other questions require an answer before more definitive recommendations can be made in such a fundamental matter as the optimal method of producing satisfactory oxygenation and removal of carbon dioxide during resuscitation. A flow chart for basic management of the airway and ventilation[35] is shown in figure 4.

Advanced management of the airway and ventilation during resuscitation

Advanced airway management is required if basic techniques are proving inadequate or more experienced personnel and equipment are available. Any technique can be described as advanced if it involves the use of adjuncts, and the European Resuscitation Council (ERC) has recently published guidelines on the subject.[34] The use of advanced airway techniques ultimately must be a personal choice depending on the training and experience of the individual concerned.

The ERC algorithm for advanced airway management (fig. 5) begins with the apnoeic patient or an unprotected airway. Clearly basic life support measures may be in progress, for example mouth-to-mouth ventilation or, if the hospitalized patient has developed an immediate need for airway management, advanced techniques may be applied in the first instance.

ADVANCED AIRWAY ADJUNCTS AND TECHNIQUES

Oral and nasopharyngeal airways

These are the simplest of the advanced airway adjuncts. They are easy to insert and help provide a

patent airway by limiting obstruction by the tongue. They need to be appropriately sized, positioned correctly and used in the relevant circumstances. Oral and nasal airways that are too short are ineffective and those that are too long may provoke laryngeal spasm. Oral airways are poorly tolerated in semi-conscious patients with active gag reflexes and may be difficult to insert in patients with clenched jaws. The nasal airway is often better tolerated in these circumstances. The oral airway can be inserted using the familiar rotational method or with a tongue depressor, which is the favoured method when dealing with children. The nasal route must be used (if at all) with extreme caution in victims of trauma, particularly if a base of skull fracture is suspected. Placement of nasal airways into the cranial vault has been described,[24] furthermore the nasal route is far more likely to cause haemorrhage than the oral route. A recent modification of the oral airway includes a pharyngeal cuff. The COPA airway (Mallinkrodt Ltd) has a standard 22-mm connector and may allow ventilation via a self-inflating bag or anaesthesia system. None of these devices offers any protection from regurgitation of gastric contents.

Cricoid pressure

It is now clear that regurgitation and aspiration must be considered as major hazards during resuscitation if the airway is unprotected. Cricoid pressure represents a protective measure during basic airway management until advanced methods can be applied. The technique is easily taught but requires re-evaluation as many who have been trained in applying it provide widely differing forces to the cricoid cartilage.[44] Recent work suggests that the original value of 44 Newtons required to prevent regurgitation is excessive and a value of approximately 30 Newtons is appropriate.[78] The presence of an oro- or nasogastric tube has been shown in cadaver studies to increase the efficiency of protection provided by cricoid pressure and it should therefore be left *in situ*.[63 78]

The use of cricoid pressure is not without potential problems. If attempts are made to ventilate a patient's lungs manually using a face mask, after applying pressure to the cricoid cartilage, there may be significant reduction in expired tidal volume and an increase in peak inspiratory airway pressure. Furthermore, complete airway obstruction may occur in up to 10% of cases.[2] This may be because of direct airway compression if cricoid pressure is excessive or applied incorrectly. Furthermore, if pressure is applied in a caudal direction (which occurs if the patient's head is flexed on a pillow) this may cause closure of the laryngeal inlet via a rotational effect on the arytenoid cartilages[12] (R. Vanner, personal communication). Cricoid pressure may also cause relaxation of the lower oesophageal sphincter making regurgitation more likely if pressure is applied poorly or released transiently.[75]

Pressure can be applied with one hand or bimanually with a hand supporting the posterior cervical spine. Recent work suggests that the single-handed technique provides just as good a view at laryngoscopy as using two hands.[15] However, supporting the cervical spine with a hand placed beneath the neck is clearly of potential benefit in any victim of trauma with a suspected broken neck. In another recent study, single-handed cricoid pressure caused significant movement of the neutrally positioned cervical spine[26] confirming that in trauma patients, at least, some posterior support of the cervical spine is indicated. Finally, if tracheal intubation is difficult or impossible, the use of other airway adjuncts (e.g. laryngeal mask airway) in the presence of cricoid pressure may be impaired.[4–8 27]

Tracheal intubation

The gold standard for advanced management of the airway during resuscitation is tracheal intubation. This provides a clear and secure airway allowing ventilation, oxygenation and suction. The skill of intubation is not easily taught, requires constant practice and the technique is not without complications if performed poorly or attempts are prolonged. There are a vast array of aids to intubation to help with the difficult airway, including laryngoscopes, bougies, stylets and light wands. Of the currently available accessories, the gum elastic bougie and McCoy laryngoscope appear to be two of the more useful, particularly in cases of difficult intubation of the trauma victim.

The gum elastic bougie has been shown to reduce significantly the failure rate of oral tracheal intubation in patients where manual in-line stabilization and cricoid pressure were applied[58] despite a slightly longer intubation time. The McCoy laryngoscope was introduced in 1993 and is available in sizes 3 and 4 for adults and more recently in sizes 1 and 2 for children. The laryngoscope causes elevation of the epiglottis from a fulcrum deep within the hypopharynx and requires less force than the Macintosh blade to expose the laryngeal structures.[49] The McCoy laryngoscope has also been shown to reduce the stress response to laryngoscopy compared with the Macintosh blade.[48] Studies have demonstrated that the laryngoscope improves the view at laryngoscopy compared with the conventional Macintosh blade and more importantly, the number of difficult views (grades 3 and 4) is reduced significantly.[16 25 43 76]

A variety of other intubation aids are available and include other laryngoscopes (e.g. Bullard, Upsherscope, Wuscope) and lighted stylets. An assortment of tracheal tubes are available with flexible tips (e.g. "Endotrol" tube), and a new stylet, the Rusch intubating stylet, allows the curve of a standard tracheal tube to be manipulated. The techniques of digital and blind nasal intubation have their advocates but both require considerable skill and constant practice. Nasal intubation is probably not appropriate for the trauma victim and furthermore, a survey of ATLS trained personnel revealed a poor success rate for intubation via this route.[50] It is now clear that in experienced hands, oral intubation of the trachea is the preferred method, particularly for the trauma patient.[18 64 66] The view at laryngoscopy is also significantly improved if the cervical collar is removed[36] and if there are enough personnel available this should be done while the neck is stabilized manually.

Confirmation of successful placement of the tracheal tube in resuscitation is of paramount importance and a variety of aids are available. The gold standard is undoubtedly capnography but misleading readings may occur because of reduced carbon dioxide delivery to the lungs in the arrested circulation. Furthermore, the apparatus is often not immediately accessible in resuscitation situations and more simple devices are appropriate. The oesophageal detector[80] is such a device. It has been modified to include the use of an evacuator bulb[59] and is highly sensitive at picking up oesophageal placement of a tracheal tube. A variety of colorimetric carbon dioxide detectors are also available, but these are not always accurate and may fail if there is not enough expired carbon dioxide. They may occasionally register a false positive result as a consequence of carbon dioxide in the stomach, either from poor basic life support techniques associated with gastric inflation or, more rarely, the presence of carbonated drinks in the gastric contents.

A more recent adjunct used for confirmation of successful tracheal intubation is the Scotti airway detector.[56] The device sends sound waves down the tracheal tube and the reflected wave is detected. If the tube is in the trachea, which is hollow, then the reflected wave is different to that detected if the tube is in the oesophagus, which is collapsed. The concept, while simple, is not without problems. The device needs calibrating and a recent study has demonstrated that it is not very specific.[47]

Finally, while the role of flexible fibreoptic laryngoscopy is limited in resuscitation situations, there are now hand-held, battery-operated fibreoptic devices (e.g. Rapiscope; Cook Critical Care Ltd) which, because they are readily portable, may find a role in confirmation of tracheal tube placement. The device has also been used to confirm correct placement of a needle or catheter passed through the cricothyroid membrane during formation of a surgical airway.[65]

Laryngeal mask airway (LMA)

This airway device (fig. 6) has revolutionized anaesthetic practice since its introduction in 1988. More than 1000 scientific studies have testified to its satisfactory and versatile application in a variety of difficult circumstances. The device provides a clear airway without the need for laryngoscopy and it can be inserted from in front of the patient if necessary, which may be useful for victims of entrapment. Ventilation is more efficient and easier than with a bag and face mask[1 53] and it can also be inserted with the neck maintained in a neutral position[13 60] for patients in whom cervical spine trauma is suspected. The technique of insertion is easily taught to nurses, paramedics and doctors[1 19 30 53 61] and the device has been used successfully by all of these groups in the management of cardiac arrest both in and outside hospital.[29 42 74] Training on manikins has been shown recently to be just as effective as training on patients when learning the insertion technique[62] and the recently introduced Portex introducer may encourage an even greater success rate for LMA insertion by non-anaesthetic personnel.[21]

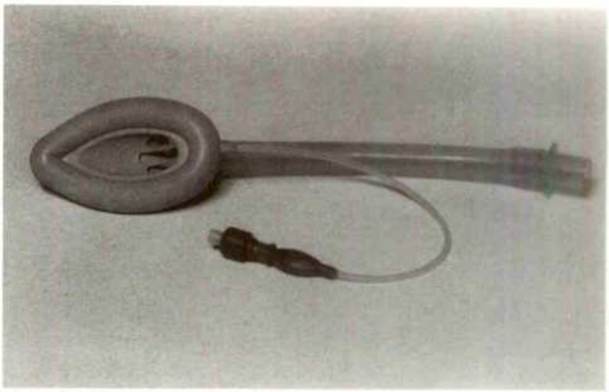

Figure 6 The laryngeal mask airway.

The LMA allows positive pressure ventilation provided it is applied carefully and airway pressures do not exceed 20–25 cm H_2O. In patients with poorly compliant lungs, for example those with pulmonary oedema, aspiration or obstructive airways disease, the lungs may not be ventilated adequately using the device. Inadequate protection of the airway is often quoted as a limitation of the LMA. However, evidence that pulmonary aspiration occurs in clinical practice is scant. In a multicentre study using the LMA at cardiac arrests the reported incidence of aspiration was only 1.5%.[74] Furthermore, the LMA protects the airway against aspiration from sources *above* the larynx.[17 41] This may have profound implications for some types of patients requiring resuscitation. In a recent study of trauma victims,[51] of those who aspirated, the vast majority aspirated blood. In nearly all cases this blood originated from sources above the larynx.

Another potential problem with the LMA is its ability to function adequately in the presence of cricoid pressure. There are several studies[4–8 27] that have suggested that cricoid pressure impedes placement of the device. Furthermore, if cricoid pressure is released and then re-applied after insertion of the LMA, its function may still be impaired.[6] A recent radiographic study[5] showed that cricoid pressure caused upward displacement of the LMA which may allow its aperture to sit against the base of the tongue, thus impairing ventilation.

Despite this, the LMA remains an extremely useful device for resuscitation. Its ease of insertion and effectiveness suggest it should be used as a first-line airway adjunct for those who do not posses the skill to intubate the trachea, such as nurses and many doctors. If oral intubation is proving difficult the device may provide a route for intubation by allowing blind passage of a tracheal tube or gum elastic bougie down the lumen and into then trachea. The success rate for this procedure is variable however, with one study quoting a success rate of 96%[37] and another only 26%.[28] Preloading the LMA with a tracheal tube or gum elastic bougie may reduce the failure rate of this technique.[20] An intubating laryngeal mask has been designed and is currently undergoing multicentre clinical studies which may improve the intubation success rate using this principle.

Oesophageal tracheal Combitube

This device (fig. 7) is a double-lumen tube which is passed blindly into the mouth and allows ventilation of the patient's lungs whether the tube enters the trachea or the oesophagus. There are apertures at a supraglottic level from the "tracheal" lumen and a distal opening from the "oesophageal" lumen. There is a small-volume distal cuff and a large-volume pharyngeal cuff. If the tube enters the trachea it can be used in the same way as any tracheal tube and the pharyngeal cuff is redundant. In the majority of cases however, the tube enters the oesophagus, in which case the distal and pharyngeal cuffs are inflated and ventilation is possible via the supraglottic side openings.

The Combitube may have certain advantages over some of the other airway adjuncts available. It requires no instruments for insertion, which makes it useful in difficult situations and locations. It occludes the oesophagus with a distal cuff and allows some "venting" of oesophageal contents via one of the two lumens. It can usually be inserted with the neck in a neutral position, making it potentially useful in trauma patients. Early studies using the device showed improvement in arterial oxygenation compared with tracheal intubation, probably because of a PEEP effect when ventilation is applied through the supraglottic apertures.[23] It has been used successfully during cardiorespiratory arrest by intensive care nurses and paramedics with some success.[9 22 71] Recently, the oesophageal detector device has been used to identify whether the Combitube has been passed into the trachea or oesophagus.[79]

Potential problems include the size of the device; it is more difficult to insert than a laryngeal mask and insertion has not been evaluated formally in the presence of a cervical collar. The technique of insertion requires training and the stomach is inflated if ventilation is applied through the wrong aperture when the device is placed in the oesophagus. Because of its size, significant airway trauma appears to occur in some patients. In recent studies blood has been noted on the Combitube after removal in 24%[46] and 45% (Gabbott, unpublished data) of patients. Airway pressures may also be higher when ventilation is attempted through the side holes. Finally, it has been suggested that ventilation is more effective with the head in a hyper-extended position.[46] This presents a problem when dealing with trauma patients where the neck has to remain in a neutral position. Recent work, however, has demonstrated that the presence of a cervical collar does not appear to significantly impair ventilation (Gabbott, unpublished data).

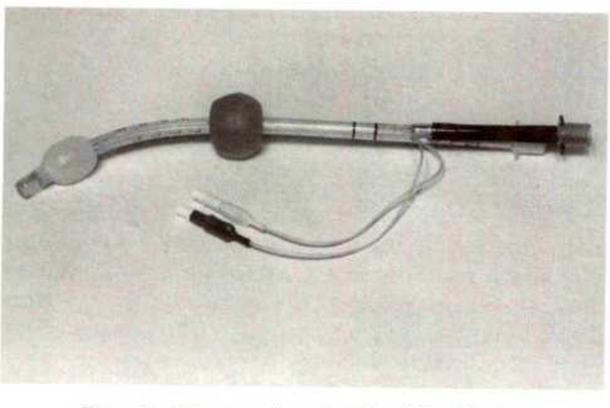

Figure 7 The oesophageal tracheal Combitube.

The Combitube therefore remains an airway adjunct that, in theory, may prove to be useful. Further assessment is required before it can be advocated on a wide scale.

Surgical airway

Resort to the surgical airway is rarely necessary but is a skill that anyone with a claim to expertise in advanced airway management should be able to perform. Direct surgical access to the trachea should be made via the cricothyroid membrane unless there is severe trauma to that region. This involves removal of cricoid pressure, if applied, which makes placement of devices such as the laryngeal mask and Combitube more successful if they are to be used as temporary oxygenation sources. Tracheostomy in the emergency situation is very difficult and probably has no place in advanced airway management during resuscitation.

There are several methods of gaining access to the airway via the cricothyroid membrane, including needle and surgical cricothyroidotomy and blind stab techniques using specifically designed equipment. These methods are hazardous in the emergency situation and should be undertaken when there is no other option and the procedure is life saving. Any of the techniques should be performed only by trained and practised operators. Training is accomplished by the use of manikins, animal larynx specimens, such as those used in the advanced trauma and advanced paediatric life support courses (ATLS and APLS) and by cadaver and post-mortem teaching if these facilities are available.

Needle cricothyroidotomy. This technique, which is the surgical airway of choice for all children because of their small airway size, involves placing a needle and catheter through the cricothyroid membrane and ventilating via a catheter which is left *in situ*. The bigger the catheter the easier is ventilation. However, the technique is only suitable to buy time while a more definitive surgical airway is created. Ventilation is difficult using a self-inflating bag but is more successful when a high pressure source of oxygen is used with inflation intermittently applied by occluding an aperture in the ventilation tubing. Careful observation of chest movement is essential to avoid barotrauma, and for the technique to be safe there should always be a clear route through the larynx and mouth for expired gases to escape. Sufficient expiration through the narrow catheter is usually not possible despite physical attempts to compress the chest.

Surgical cricothyroidotomy. This technique is gaining in popularity, particularly in the trauma setting, although documented evidence of its effectiveness in cardiopulmonary resuscitation is lacking. The procedure involves incision of the cricothyroid membrane under direct vision and insertion of an appropriately sized tracheal tube. Ventilation is highly effective and a secure airway is created.

While surgical cricothyroidotomy appears to be a simple technique, it is not without complications, with some studies reporting a total failure rate of up to 12%.[67] Others, however, have reported a much lower failure rate[55] and this may depend on the skill of the operator. Precautions that can be taken to reduce complications include limiting the lateral extent of any horizontal incision, incising the inferior part of the cricothyroid membrane in an attempt to avoid the cricothyroid arteries, and directing the scalpel blade away from the head to avoid vocal cord damage.

The technique is indicated in cases when life-threatening upper airway obstruction is present and all other attempts to secure the airway and ventilate the patient's lungs have failed. Persistent attempts at tracheal intubation may result in worsening hypoxia and in these cases an early decision to create a surgical airway should be made. Because of the high complication rate significant training and experience are required.

Blind stab techniques. This method uses a single stab technique through the skin, subcutaneous tissues and cricothyroid membrane. Several commercially available kits (Portex, Cook Critical Care, Rusch) allow access to the airway using the technique. Most are simply large trocars over which a short, wide-bore tube is passed with a standard 22-mm connector. Some kits incorporate the use of guide wires and others use a more graded, dilational system.

Whichever product is used it is apparent that the technique may present considerable problems if it is not appropriately taught. Furthermore, access to the airway in the patient who is attempting to breath with a larynx that is constantly moving under the skin can be very difficult. Nevertheless, the concept of a readily available, rapid access device that does not require additional pieces of equipment for insertion is to be commended. Only by using and practising inserting such devices can appropriate experience be gained.

ADVANCED MANAGEMENT OF VENTILATION

Advanced ventilation methods are designed to overcome the shortcomings of expired air resuscitation techniques. However, if applied poorly they can be less effective and more hazardous than well executed basic techniques.

During cardiopulmonary resuscitation oxygenation is paramount; carbon dioxide delivery is likely to be low thus eliminating the requirements for large tidal volumes[11] and lung compliance may be considerably reduced requiring higher inflation pressures.

There is some experimental evidence suggesting that ventilation itself may not be of paramount importance during the first few minutes after cardiac arrest. Indeed chest compression alone may generate sufficient tidal volumes for adequate oxygenation provided the airway is patent and a high inspired oxygen source is provided.[14 72] This may be significant during the first few minutes after cardiac arrest, particularly if first responders are unwilling or unable to provide suitable ventilatory assistance.

Work in humans using active compression–decompression CPR has also demonstrated the potentially satisfactory tidal volumes generated by this technique alone, allowing sufficient ventilation to maintain blood-gas values at near normal levels provided the airway remains patent.[38]

Ventilation devices

Devices for advanced management of ventilation include the self-inflating bag–valve–mask, anaesthesia systems, oxygen powered and automatic resuscitators and devices for transtracheal jet ventilation. These latter devices allow some ventilation via a cannula placed in the cricothyroid membrane, as described above. The system uses a high pressure oxygen source and a purpose designed injector. The method is relatively inefficient at eliminating carbon dioxide, although in cardiac arrest situations this may not be of much importance initially.

The self-inflating bag–valve devices are still the mainstay of ventilation for many during resuscitation. They are portable, robust and convenient but require considerable skill when used with a face mask, and a two-rescuer technique has therefore been recommended.[3 10] The importance of generating large tidal volumes has now been questioned, however, and a single-rescuer technique may be appropriate with smaller lung volumes equally acceptable. Of greater importance is that oxygen is provided at or close to an $F\mathrm{I}_{\mathrm{O}_2}$ of 1.0. This can only be achieved effectively by the use of large volume oxygen reservoir bags or the use of a demand valve.

Anaesthesia systems and manually triggered ventilators have a limited place in resuscitation as they are either in a fixed location or require the operator's hands for providing ventilation, or both. Automatic ventilators, however, give the best all round option; they provide an $F\mathrm{I}_{\mathrm{O}_2}$ of 1.0, consistent tidal volumes and ventilatory frequencies, and free the rescuer's hands for other tasks. Many sophisticated models are now available[57] some of which incorporate air–oxygen mix facilities, the ability to provide PEEP, disconnect alarms, variable I:E ratios and airway pressure monitoring facilities. They are compact, robust and lightweight and function under a variety of climactic and environmental conditions. The only drawback is the relatively large consumption of oxygen that may be used as the driving gas. This may cause problems when no piped gas is available and gas cylinders have to be used.

A flow chart for the advanced management of the airway and ventilation[34] is shown in figure 5.

Advanced life support guidelines

C. E. ROBERTSON

In 1992, the European Resuscitation Council (ERC) published guidelines for advanced life support (ALS). These guidelines were produced by an international group of experts and based on consensus views of the available literature. This European initiative brought together individuals and organizations in a unique endeavour. However, it was recognized that because of the changing nature and incomplete knowledge in the field of cardiopulmonary resuscitation (CPR), that regular review and re-assessment would be required.

In the past 5 yr considerable changes have occurred. Some of the answers to previously unknown and difficult problems, such as the potential value of high-dose catecholamines and use of alternative techniques to increase antegrade blood flow during closed chest compression, are now available. Important new advances have occurred in the technology associated with resuscitation, in particular defibrillation. Manual defibrillators require a level of rhythm recognition and interpretation that many health care professionals find difficult. Semi-automated and automated defibrillators are now widely available, particularly in the pre-hospital environment. The 1992 guidelines were not designed with these devices in mind.

For all of these reasons, a review of the guidelines was both apposite and timely. The formation of the International Liaison Committee on Resuscitation (ILCOR) has facilitated this process by making possible worldwide cooperation and discussion. Representatives from North America, Europe, Southern Africa and Australasia have collaborated to produce the ILCOR advisory statements on resuscitation which were published in April 1997. This article summarizes the ALS component of the advisory statements with particular reference to their use in the UK. The UK, under the aegis of the Resuscitation Council (UK), has accepted the task of assessing these new ALS guidelines on behalf of the ERC under the title "The 1997 Guidelines for use in the UK".

General principles

One of the most difficult tasks of educators is to maintain a consistent and logical approach within the framework of an easily retained message. The limitations of guideline production and use must be acknowledged. Slavish adherence to rigid instructions is rarely practicable or indeed advisable. As often happens in medicine, interpretation with commonsense and an appreciation of intent is necessary.

This is particularly the case in the field of resuscitation where our knowledge is at best incomplete. It is hoped that these guidelines, while offering a clear approach, will also allow individuals with specialist knowledge the opportunity to modify them according to the level of their expertise and the specific clinical situation or environment in which they are used.

The commonest cause of adult sudden cardiac arrest is ischaemic heart disease. The majority of individuals who die from an acute coronary syndrome do so before reaching hospital and emphasis on prevention of cardiac arrest is essential. In relation to this, the correct and timely management of peri-arrest arrhythmias may prevent the development of cardiac arrest[41,41a] (see also page 198).

A small, but important, group of patients develop cardiac arrest in special circumstances; examples include trauma, hypothermia, immersion, drug overdose, anaphylaxis, hypovolaemia, etc. While the ALS guidelines are universally applicable, in these situations specific modifications may be needed to increase the chances of success.

Specific ALS interventions

TRANSTHORACIC DEFIBRILLATION

By far the commonest primary arrhythmia in adult cardiac arrest is ventricular fibrillation (VF).[2,51] In some patients, this is preceded by a short period of ventricular tachycardia (VT) which deteriorates in waveform to VF. Early detection and treatment of these rhythms is central to the chances of successful outcome. The majority of eventual survivors of cardiac arrest come from this group.[21,59] The more rapidly a patient can be defibrillated in these

(*Br. J. Anaesth.* 1997; **79**: 172–177).

Key words
Complications, cardiac arrest. Heart, resuscitation. Heart, defibrillators. Advanced life support.

circumstances, the greater the chance of obtaining a perfusing cardiac rhythm and the higher the ultimate success rate. It has been estimated that the chances of successful defibrillation decline by approximately 2–7% with each minute that a patient remains in cardiac arrest.[38] This decline reflects rapid depletion of myocardial high energy phosphate stores,[44] and is mirrored in the deterioration of the amplitude and characteristics of the VF waveform.[42] Basic life support (BLS) can slow the rate of decline but does not reverse it. As a consequence, the priority is to reduce the delay between the onset of cardiac arrest and defibrillation.

One of the most interesting developments has been the use of new techniques during defibrillation. These include altering the waveform of the shock, automatically adjusting the energy administered according to transthoracic impedance or producing sequentially overlapping shocks with rapidly shifting electrical vectors.[5 23 32] With most conventional manual defibrillators, the defibrillation waveform used has a damped monophasic sinusoidal pattern. New machines delivering biphasic waveforms can, with lower energies, produce shocks with similar success rates. This technique has the advantage that the inevitable myocardial injury produced by defibrillation is reduced.

An alternative technique is available with some automated defibrillators. These measure the patient's transthoracic impedance immediately before administration of shock and then deliver a shock based on current flow. Current-based defibrillation is particularly useful in patients who have unusually high or low transthoracic impedance values.

Irrespective of the type of machine used, the correct defibrillation technique is important to reduce transthoracic impedance and maximize the chance of success. Only a small proportion of the delivered electrical energy traverses the heart during transthoracic defibrillation so that efforts to maximize this are important. Common faults include inadequate contact of the paddles or self-adhesive pads with the chest wall, failure or inadequate use of couplants to aid current passage between the paddles and chest wall, and faulty paddle positioning or size.[1 3 30 53] One paddle should be placed to the right of the upper part of the sternum below the clavicle, the other just outside the position of the normal cardiac apex (V4–5 position). Placement over the breast tissue in female patients should be avoided to reduce transthoracic impedance. Other positions, such as apex-posterior, can be considered if the standard position is unsuccessful. Polarity of the electrodes appears to influence success with internal implantable defibrillators, but during transthoracic defibrillation the polarity of the paddles is unimportant.

On a practical note, it is important to realize that after administration of a defibrillating shock there is often a delay of a few seconds before an ECG trace of diagnostic quality is obtained. Furthermore, even when a electrical rhythm compatible with cardiac output is obtained after a defibrillating shock, temporary impairment of cardiac contractility is often present and the first few cardiac cycles may be associated with a weak, or difficult to palpate, central pulse. It is important to recognize these phenomena and allow for them rather than concluding that electromechanical dissociation has developed.

CPR TECHNIQUES

Several new experimental techniques have been investigated and evaluated over the past few years; these include simultaneous compression and ventilation, high impulse external chest compression, interposed abdominal compression, vest CPR and active compression/decompression CPR.[15] Some of these techniques have been shown experimentally to improve the haemodynamic state associated with CPR and in some cases to improve survival in animal models. It is disappointing that at present there are no clinical data showing unequivocal improvement in outcome in large-scale human studies with any of these techniques.[50 56] Consequently, the new guidelines do not recommend any change in the technique of closed chest compression.

AIRWAY MANAGEMENT AND VENTILATION

In 1996, an ERC working group published guidelines for the advanced management of the airway and ventilation during CPR.[6] These are incorporated into the advanced life support guidelines and their detailed aspects are covered separately in this issue of the journal.

After cardiac arrest and during CPR, normal pulmonary physiological characteristics are altered. There is an increase in deadspace and a reduction in lung compliance because of the development of pulmonary oedema. These changes may compromise gas exchange and serve to focus attention on the delivery of oxygenation and ventilation of the patient's lungs. The aim should be to provide a fractional inspired oxygen concentration ($F\text{I}_{\text{O}_2}$) of 1.0. Fortuitously, carbon dioxide production and its delivery to the pulmonary circulation is limited by the relatively low cardiac output achieved during CPR. As a consequence, high tidal volumes are unnecessary to achieve adequate carbon dioxide excretion and the prevention of hypercapnia. This situation may, however, require some modification if carbon dioxide producing buffers are administered (see below) and relative increases in minute ventilation are required to prevent carbon dioxide build-up and the development of hypercapnic acidosis.

DRUG DELIVERY DURING CPR

The optimal method of drug administration during CPR is still the pervenous route.[24] Central venous cannulae can deliver drugs rapidly and efficiently to the central circulation. In general, provided cardiac arrest has not ensued as a consequence of hypovolaemia, the central veins are often full; nevertheless, central venous cannulation by whatever route (e.g. internal jugular or subclavian) requires considerable technical proficiency. The risks associated with the technique of central cannula insertion are significant. Well recognized complications include pneumothorax (with the possibility of the development of tension), arterial puncture, air embolus and catheter malposition. Some of these can be life threatening and early detection may be difficult. Obviously, if a central venous cannula is already *in situ*, it should be used. Otherwise, for an individual patient, the decision to attempt central venous cannulation depends on the skill of the operator, available equipment, nature of the surrounding events and time scale. If the decision is made to perform central venous cannulation it must never delay defibrillation attempts, performance of CPR or security of the airway.

Where a peripheral venous route is used, a flush of 20–50 ml of 0.9% saline is given after drug administration to expedite entry to the central circulation. Administration of drugs by the tracheal route is theoretically attractive, particularly if there is no immediate access to the systemic circulation. During the management of cardiac arrest, tracheal intubation frequently precedes venous cannulation, particularly in patients where venous access is rendered difficult by obesity or previous drug use. Unfortunately, the early promise shown by tracheal drug administration has not been confirmed. Impaired absorption and unpredictable pharmacodynamics means that drug administration by this route remains a second line approach.

Drugs which can be given by this route are also limited, currently to adrenaline, lignocaine and atropine. It is recommended that doses of 2–3 times the standard i.v. dose are given, diluted up to a total volume of at least 10 ml in 0.9% saline. After administration, five ventilations are given in an attempt to maximize absorption from the distal bronchial tree. Theoretically, administration of the agent by deep endobronchial application would be advantageous. This would necessitate the use of a catheter inserted via the tracheal tube. Surprisingly, for lignocaine, no advantage was demonstrated from deep endobronchial administration.

DRUG THERAPY DURING CPR

Over 100 yr ago, adrenaline was used to produce peripheral vasoconstriction and re-start the hearts of animals in asystole. For the past 40 yr adrenergic agents have been advocated as the mainstay of pharmacological therapy in cardiac arrest. There is no doubt that experimentally adrenaline (and other adrenergic agonists) can improve myocardial and cerebral blood flow.[45] In animal studies this can result in improved resuscitation success rates. These effects are dose-dependent and higher doses are more effective than the "standard" dose of 1 mg. Unfortunately, the human clinical experience is much less clearcut. There is little evidence that adrenaline unequivocally improves survival or neurological recovery rates in humans after cardiac arrest.[26, 62] Although slightly increased rates of spontaneous circulation have been seen in some clinical studies with high-dose adrenaline, there was no overall improvement in survival rate.[7, 10, 40, 55]

It is interesting to conjecture why there are these marked differences between experimental and clinical results. They may in part reflect the differences in underlying pathology between the human and animal heart, together with the relatively long periods of cardiac arrest before ALS procedures enable adrenaline to be given in the clinical setting. Furthermore, it is possible that higher doses of adrenaline could be counter-productive in the post-resuscitation period by increasing myocardial oxygen consumption, adversely affecting patterns of endocardial, epicardial and pulmonary blood flows, and inducing the pattern of myocardial injury known as contraction band necrosis.[46, 58]

To date, there has been no randomized, controlled study in humans comparing standard dose adrenaline (1 mg every 3 min) with placebo of sufficient power to provide an unequivocal result. Pending this, it is recommended that the indication, dose and time intervals between doses of adrenaline remain unchanged.

The risks of routinely administering adrenaline to patients in whom cardiac arrest is provoked by, or associated with, solvent abuse, cocaine and other sympathomimetic drugs should also be remembered.[37, 39, 52]

The use of antiarrhythmic agents to prevent arrhythmias is well established. Their use to facilitate defibrillation is, however, much less clear. There is no doubt that animal models have dramatically improved our knowledge of the mechanisms of arrhythmogenesis and antiarrhythmic drug actions.[4] As with adrenaline, however, extrapolation from the animal to the clinical model is fraught with problems.

Of all the antiarrhythmic agents used in cardiac arrest, we know more about lignocaine than any other drug. Initial concerns that lignocaine increased the ventricular defibrillation threshold are probably more related to the experimental technique than an effect of the drug.[13, 17, 20, 31, 43] In humans, the energy requirements for defibrillation were not increased when lignocaine was given.[36] Whether lignocaine was more efficacious than other agents, such as bretylium, is unknown. The CALIBRE study, a multicentre study which is currently evaluating these two agents in this situation, is now underway. Pending this, it is recommended that no change be made in relation to previous recommendations on the use of lignocaine, bretylium or other antiarrhythmic agents.

The use of atropine in the treatment of haemodynamically compromising bradyarrhythmias and some forms of heart block is well established.[41] Atropine has previously been advocated in the management of asystole on the basis that an increase in vagal tone could produce arrhythmias or reduce the potential efficacy of other therapies in re-starting an electrical rhythm.[61] Evidence of efficacy of atropine in asystole is limited to small series and case reports.[8, 16, 25, 57] Nevertheless, the prognosis of asystolic states is so poor and the likelihood of significant adverse effects produced by atropine so limited, that its use in this situation can be considered. In healthy human volunteers, a single dose of 3 mg i.v. is sufficient to block vagal activity completely and this dose is recommended if atropine is considered for asystole.[12]

Provided that effective basic life support is performed, arterial blood-gas analysis shows neither rapid nor severe development of acidosis during cardiorespiratory arrest in previously healthy individuals.[25,54] Arterial blood-gas analysis is commonly performed to assess acid–base status, but alone may be misleading. Even co-terminously measuring arterial and mixed central venous blood-gas samples may be of little value in estimating the internal milieu of myocardial and cerebral intracellular acid–base status.[11,29,34,60]

In the past, administration of sodium bicarbonate as a buffer was advised to reverse the potentially deleterious effects of acidosis. Potential adverse effects of sodium bicarbonate administration include alkalaemia, hyperosmolarity and carbon dioxide production. Other agents, such as sodium carbonate, Carbicarb (a mixture of sodium carbonate and sodium bicarbonate), tromethamine (THAM) and tribonate (a mixture of sodium bicarbonate, THAM, phosphate and acetate) have been suggested to minimize some of these effects.[22] However, there is no clinical evidence to suggest that carbon dioxide consuming buffers, or indeed any buffer, are effective in increasing survival rates after human cardiac arrest.[19,33,35] The best method of reversing acidosis associated with cardiac arrest is to restore spontaneous circulation. At present, in the UK, sodium bicarbonate remains the buffer of choice. It is suggested that its judicious use is limited to patients with severe acidosis (arterial pH less than 7.1 and base deficit less than −10) and to cardiac arrest occurring in special circumstances, such as hyperkalaemia or tricyclic antidepressant overdose.

The universal ALS algorithm

There is now a single algorithm for ALS management; it is applicable for health care providers using manual, semi-automatic or automatic defibrillators (fig. 1). Each step of the algorithm presupposes that the one before has been unsuccessful.

The route of access to the ALS algorithm depends primarily on the events surrounding the cardiac arrest. In many situations, such as out-of-hospital cardiac arrest, basic life support will already have been started. This must continue while the monitor/defibrillator is being attached. In patients who are already monitored, clinical and electrocardiographic detection of cardiac arrest should be nearly simultaneous. In these situations, patients who have had a witnessed collapse can have a single precordial thump administered pending attachment of the monitor/defibrillator or if there is any delay in administration of the first defibrillating shock.[9,47]

Analysis of the ECG rhythm must take place within the clinical context. Movement artefact, lead disconnection and electrical interference can all mimic cardiac arrest rhythms. For the rescuer with a manual defibrillator, the crucial decision is whether or not the rhythm present is VF/VT. If VF/VT is suspected, defibrillation must occur without delay. The first shock is given with an energy level of 200 J for a standard monophasic shock, or its equivalent if a biphasic waveform in used. If the first defibrillating shock is unsuccessful, a shock of the same energy (200 J) is repeated. If still unsuccessful a third shock is given, this time at 360 J.

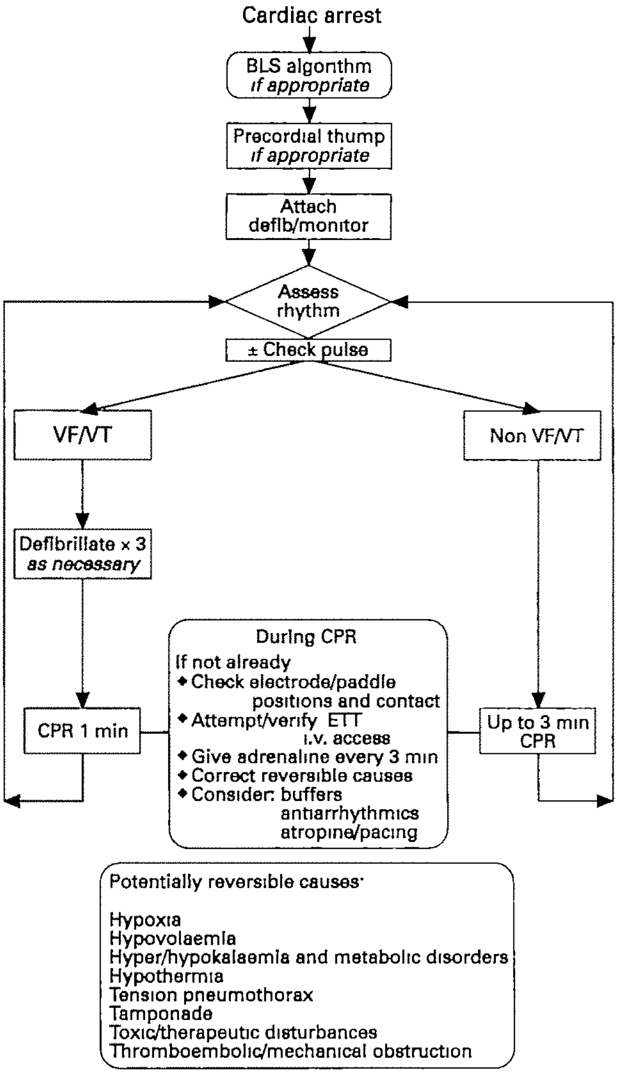

Figure 1 Algorithm for advanced life support management. BLS=Basic life support

A check of a major pulse is performed if, after a defibrillating shock, an ECG rhythm compatible with cardiac output is obtained. If, however, the monitor/defibrillator indicates that VF persists, then the additional shocks in the sequence of three can be administered without a further pulse check.

With modern monitor/defibrillators it is possible, if necessary, to administer the first three shocks within a period of 60 s, and in the majority of patients who are treated successfully, defibrillation occurs after one of the first three shocks. If the first sequence of three shocks is unsuccessful, the best chance for restoring a perfusing rhythm is still defibrillation but correction of reversible causes or aggravating factors, and attempts to maintain myocardial and cerebral perfusion and viability, are indicated at this stage.

Potential causes or aggravating factors leading to persistent VF/VT may include electrolyte imbalance, hypothermia and drugs or toxic agents for which specific therapy may be required (see fig. 1). These interventions, together with checking defibrillating paddle/electrode positions and contacts, should occur during the 1-min period of CPR.

During this time, attempts are made to secure advanced airway management and ventilation and to institute venous access. The first dose of adrenaline is given.

It is unlikely that even with a highly trained team all of these aspects will be completed within this first CPR interval, but further opportunity will occur with the next cycle.

The ECG rhythm is then re-assessed. If VF is still present, the next sequence of defibrillating shocks is started without delay. These shocks are all at 360 J (or equivalent).

Provided that resuscitation was started appropriately, sequential loops of the left-hand side of the algorithm are continued, allowing further sequences of defibrillating shocks, CPR and the ability to perform/secure advanced airway and ventilation techniques and drug delivery. As long as resuscitation has been started appropriately, it should not normally be abandoned while the ECG rhythm is still recognizably VF/VT.

If at the time of initial rhythm analysis, VF/VT can be positively excluded, clearly defibrillation is not appropriate. In this situation, the right-hand side of the algorithm is followed. These patients may have asystole or electromechanical dissociation (EMD). Any electrical rhythm associated with cardiac arrest will, if untreated, deteriorate to asystole. The prognosis for these rhythms is, in general, much less favourable[14,27] but nevertheless there are some situations where they have been provoked by remediable conditions which, if detected and treated promptly, may lead to success. The common causes are listed in figure 1 and may be recalled under the headings of the 5 H's and 4 T's.

Cardiac pacing may be of value in patients with extreme bradyarrhythmia. Its efficacy in true asystole is unproved, except in cases of trifascicular block where p waves are present. If pacing is contemplated and delay occurs before its institution, external cardiac percussion (fist pacing) may be effective in producing cardiac output, particularly in those situations where myocardial contractility has not been critically compromised.[18,48,49] While the search for, and correction of, these potential causes of arrest are underway, basic life support with advanced airway management and ventilation, venous access, etc, should occur as before, and adrenaline is administered every 3 min.

After 3 min of CPR, the ECG rhythm is re-assessed. If VF/VT has developed, then the left-hand side of the algorithm is followed. If a non-VF/VT rhythm still persists, loops of the right-hand side of the algorithm continue for as long as is considered appropriate for resuscitation to continue.

Paediatric and neonatal life support

D. A. ZIDEMAN

Resuscitation of infants and children is different from adult resuscitation. Although there may be many similarities in the methodologies used in the resuscitation procedures with those used in adults, paediatric life support is governed by the fact that it begins from a different starting point. Adult sequences are based on the observation that the majority of cases are primarily cardiac in origin; arrest is therefore rapid and immediate in onset giving little or no warning of occurrence and usually requiring rapid defibrillation to achieve any measure of success. In infants and children the cause is usually primarily a respiratory event which leads to the final cardiac arrest if not recognized and dealt with promptly.[43 46 95 96 105] Primary cardiac arrest in children is rare and ventricular fibrillation and ventricular tachycardia have been reported in less than 15% of the young.[4 40 64] The aetiology and pathogenesis of sudden death in this age group is therefore important. Many children have a relatively long "pre-arrest" phase, cardiac arrest signalling the end of a progressive physiological decline. It could be argued that in such events many deaths could be prevented by early recognition and aggressive therapy in this "pre-arrest" phase but, unfortunately, some remain irreversible despite all efforts.

Trauma is the one cause of cardiac arrest that occurs in both children and adults and is the most common cause of death in the first four decades of life. It could be argued that trauma is preventable and, more importantly, cardiac arrest secondary to trauma can in some cases be prevented by careful correct management of the airway, breathing and circulation of the trauma victim before managing the secondary injuries.

The outcome of paediatric life support is disappointingly low with survival rates between 3 and 17%.[23 25 32 43 46 57 64 71 82 90 98 105] These poor survival results are even more dismal when the majority show significant neurological impairment after arrest. The variability in results is attributed to whether the primary event was respiratory in nature, which has a better outcome,[25 55 98] or a primary cardiac event, which has a worse prognosis.[25 32 72] Furthermore, events occurring outside hospital[25 31 32 57 68 72 84 96 98 99] have a poorer outcome than those occurring in hospital.[22 24 32 34 55 58 72 104 105] Audit and analysis of paediatric life support events are complex. Resuscitation is relatively uncommon and many studies have collected data for several years and still have small sample sizes. In the BRESUS study in the UK, only 2% of victims were aged less than 14 yr.[100] In an American study surveying 15 yr of prehospital events, only 7% of victims were less than 30 yr of age and 3.7% were less than 8 yr old.[4] Furthermore, definitions used in evaluating events are inconsistent and often not comparable from study to study. In an effort to improve our knowledge of paediatric life support and its outcome, a revised reporting template was formulated. It is hoped that these paediatric Utstein style guidelines[106] will help to standardize the reporting of outcomes of paediatric life support and thereby provide an evidence-based practice of comparable data sets to establish the true worth of these events.

One conclusion is clear; infants and children who progress to cardiac arrest have a very poor prognosis. Because of the aetiology of resuscitation in these age groups it is important that the pre-event symptoms are recognized early and treated effectively before respiratory collapse and the inevitable cardiac arrest. Therefore, in paediatric life support, prevention and early recognition of the impending event are major factors for overall survival.

Paediatric life support

Guidelines for paediatric life support have been published by several national organizations.[1 26 51 73 87] In 1992, an International Liaison Group was established to examine the basic scientific data, analyse national differences and formulate recommendations based on science which would form the basis of international guidelines to be used in the future by individual national organizations. In 1997 the International Liaison Committee on Resuscitation (ILCOR), a multi-national committee comprised of members representing most of the major national resuscitation organizations, published a series of advisory statements, including a paediatric statement.[47] In paediatric life support the committee found very few areas of serious controversy. It is

hoped that the paediatric ILCOR advisory statement will form the foundation to build national procedures and to highlight areas which need further scientific investigation and research.

Age definitions

Paediatric life support deals with the resuscitation of infants and children. Because of the wide variation in anatomy, physiology and epidemiology throughout the paediatric age range, it is therefore important to define various age ranges in an effort to rationalize treatment.

ANATOMY

The size of a child is an obvious important consideration in determining the practical resuscitation procedure to be followed. Two categories are suggested: (1) infants less than 1 yr of age; and (2) children aged 1–8 yr.

The upper age limit of 8 yr for children has been proposed as a watershed, particularly in relation to the technique of chest compression. A small child less than 8 yr of age probably receives adequate chest compressions using a "one-handed" technique. An older or larger child probably requires a "two-handed" (adult) technique to achieve adequate depth of compression. None the less, because of the variability in size of children, no definitive upper age limit can be set and the rescuer must judge the effectiveness of the resuscitation and adapt the technique appropriately.

PHYSIOLOGY

From a physiological point of view it could be suggested that the upper age limit should be puberty. Although this has been considered carefully, evidence has shown that the physiological changes of puberty have little effect on paediatric life support. In the newborn the physiological differences are obvious; the non-compliant newborn lungs require a unique sequence of resuscitation procedures, which although superficially still follow the same "ABC" sequence, require the development of a different practice.

EPIDEMIOLOGY

Much has already been written on the differences in resuscitation epidemiology between adults and children. Considering the epidemiology, it could be suggested that older children, adolescents and young adults have the same underlying causes of collapse and arrest which are more aligned to paediatric than adult procedures. In the newborn it is important to establish the first breath and maintain effective ventilation and oxygenation. In the infant and child, airway and breathing problems predominate and lead rapidly to bradycardia and asystolic cardiac arrest. Primary cardiac events should be considered only when there is a pre-existing history of heart disease. The conclusion is simple; the resuscitation sequence must be determined by the most likely cause of the event. The common aims of all forms of paediatric life support are establishment of a clear airway and oxygenation of the lungs; these are prerequisite to all other forms of treatment.

Basic life support (fig. 1)

ASSESS RESPONSIVENESS

Before starting a resuscitation procedure it is vital to evaluate the situation for any danger or physical hazards. The first step is to assess the level of responsiveness. Gentle but firm stimulation must be given and this alone may be sufficient to awaken the child or stimulate respiration. Infants should not be shaken vigorously nor children with a suspected spinal injury. If the child is unresponsive, shout for help. Only move the child if he is in a dangerous location.

AIRWAY

The tongue is the most common cause of airway obstruction in children.[88] Simple head tilt–chin lift or jaw thrust manoeuvres establish the paediatric

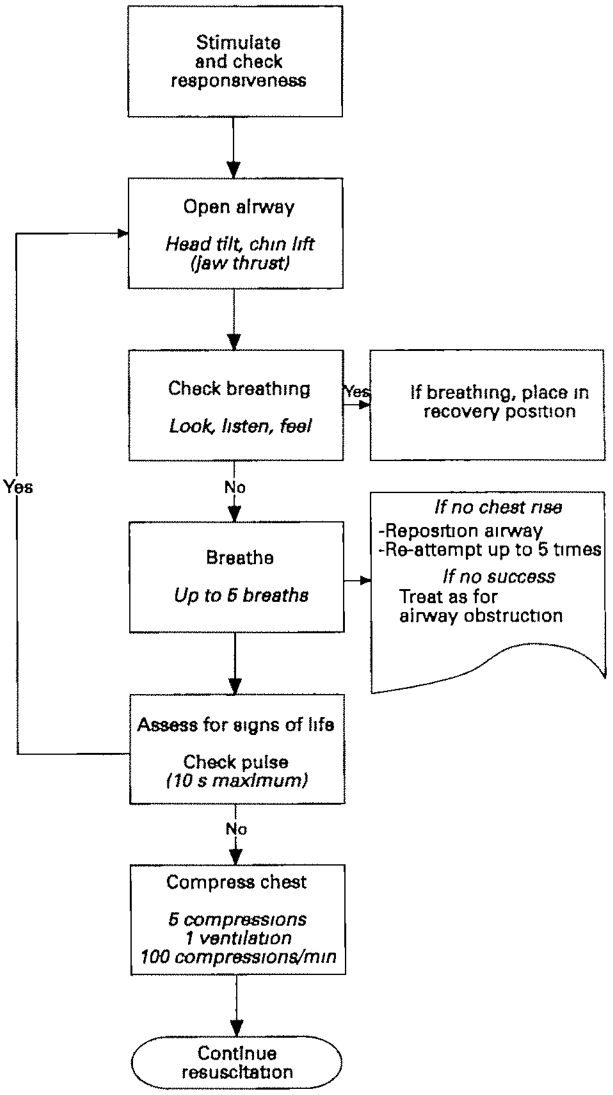

Figure 1 Algorithm for paediatric basic life support.

airway; only the jaw thrust procedure is recommended when trauma is the cause of collapse. More recently, a tongue–jaw lift manoeuvre has been described accompanied by visual inspection of the mouth,[86] but further evaluation has yet to establish the value of this procedure.

If a foreign body is obstructing the airway it should be removed carefully under direct vision. Blind probing of the child's airway is likely to impact the object further or to cause tissue damage, and should be discouraged. Where complete upper airway obstruction has occurred as a result of inhalation of a foreign body, the object is probably too far into the airway to be seen or removed by simple means and advanced airway procedures are needed.

BREATHING

Assessing effective breathing is very difficult[6] and subject to errors. Three methods are recommended in assessing respiration.

(1) Look for chest and abdominal movement.

This detects physical movement, but it may not be coordinated and effective to move air in and out of the lungs.

(2) Feel at mouth and nose for air movement.

This confirms the effectiveness of the chest movement.

(3) Listen over the airway for breath sounds.

An important manoeuvre which indicates if the child has large or small airway problems. Absence or lessening of airway noise could mean that the problem is improving; alternatively, it could indicate that the child is moving less air past the obstruction and that the situation is getting worse.

If the infant or child is not breathing, it is essential to commence expired air ventilation immediately. The mouth of the rescuer applied to the mouth and nose of the infant has been the conventional teaching, but recently the effectiveness of the mouth of the rescuer applied to the nose of the infant has been described.[91 97] In the child, mouth-to-mouth expired air ventilation is recommended. A minimum of two but up to five breaths may be required. In some situations two breaths may be sufficient to re-establish signs of life and spontaneous respiration. Because of the probable hypoxic aetiology of the event, five breaths are considered the optimal number of breaths to oxygenate a child. The breaths should be slow, each lasting 1–1.5 s. These slow breaths minimize gastric distension from high-pressure, high-flow ventilation.[62 63] It is also important not to ventilate with excessive tidal volumes as this may lead to gastric distension and regurgitation of gastric contents.[11] A simple and effective guideline is to observe the child's chest and to stop ventilation when the chest rises to the equivalent of a deep breath. If the chest does not rise when attempting ventilation, realign the airway (over extension of the neck may occlude the airway) or consider clearing the airway using the procedures described in "foreign body airway obstruction" below.

CIRCULATION

Assessment of the circulation at this point in the resuscitation sequence has conventionally been by checking the pulse. Assessment of the brachial pulse is recommended in infants[17] and assessment of the carotid pulse in children. Alternatively, the femoral artery can be palpated. Despite its apparent simplicity the lay rescuer and even experienced health care providers have difficulty in performing the pulse check accurately[12 60 65 66] and the value of the pulse check during resuscitation has been questioned. For example, if an unresponsive infant does not show obvious signs of recovery after expired air ventilation is there any point in delaying chest compressions for a pulse check? The concept of not performing a pulse check before commencing chest compressions is difficult and it may appear illogical not to formally establish cardiac arrest before commencing chest compressions.

The current recommendations cover the difficulty in making an accurate pulse check by stating that if a pulse is not confidently detected within 10 s, further resuscitation interventions should not be delayed. Furthermore, in the infant, if the pulse rate is slow (less than $1\ s^{-1}$ or $60\ min^{-1}$), cardiac output should be considered to be ineffective and full resuscitation commenced.

CHEST COMPRESSIONS

Chest compressions are performed on the lower half of the sternum. In the infant, compression is performed using two fingers placed 1 finger's breadth below an imaginary line joining the nipples. In the child, the heel of one hand is used and positioned 1 finger's breadth up from the xiphisternum. In the older child (more than 8 yr of age) and in the larger young child, this one-handed compression technique may be found to be inadequate and the two-handed compression technique (as used in adult resuscitation) may be required to produce effective chest compression.

The depth of compression should be judged in relative rather than absolute terms. For infants and small children it is recommended to compress the chest to one-third of its resting diameter. The efficacy of chest compression can be judged by palpation of the femoral vessels but this may reflect venous and not arterial blood pulsation.[8] More effective assessment can be made by analysis of the arterial waveform or evaluation of the expired carbon dioxide tracing.

The compression rate is 100 compressions per minute. A single expired air ventilation should be given after every five compressions. This provides adequate ventilation and oxygenation for the infant or child. In the older child, where two hands are required for effective chest compression, the adult ratio of 15 compressions to two ventilations can be used, compressing the chest at a rate of 100 per minute.

Activation of the emergency medical services

Ideally, the call for help given during the assessment of responsiveness should have activated the emergency medical services. In reality this is not always the case, and the priority in paediatric life support is to establish an airway, commence effective breathing and circulate oxygenated blood. In paediatric life support therefore, resuscitation is started and the emergency medical services activated after approximately 1 min of resuscitation. Thus paediatric procedures have adapted the "phone fast" rather than "phone first" philosophy based on aetiological considerations of the resuscitation event. This is a general recommendation but local emergency medical services' circumstances or the availability of "dispatcher-guided CPR" may override these recommendations.

Basic life support must continue without further interruption until experienced help arrives or until signs of life return.

Foreign body airway obstruction

Aspiration of food or vomit, or inhalation of a foreign body compromises the paediatric airway. Spontaneous coughing to clear the material should be encouraged but if this fails, back blows and chest thrusts in infants and back blows together with alternate cycles of chest thrusts and abdominal thrusts in children may provide sufficient vibration to loosen the material and enough expiratory force to expel the obstruction. Abdominal thrusts are not recommended in infants less than 1 yr of age as damage to the abdominal contents may occur. The importance of checking the mouth, formally opening the airway and attempting expired air ventilation after each cycle has been highlighted by the need to assess constantly that the airway is actually obstructed. These checks are also required to assess if the clearing manoeuvres have dislodged the material sufficiently to allow air pass the obstruction. The precise sequence for relief of airway obstruction has not been assessed formally.

Advanced life support (fig. 2)

Basic life support in an essential prerequisite to the paediatric life support sequence. Advanced life support provides the definitive management of the various resuscitation modalities in the hope of restoring spontaneous cardiac activity. Unlike adult resuscitation, the paediatric procedure emphasizes the importance of the airway and oxygenation. Furthermore, the paediatric procedures regard asystole as the primary arrythmia; ventricular fibrillation has been documented in less than 10% of paediatric arrest calls,[4,23,25,34,103] even when the cardiac rhythm is assessed within 6 min of activation of the emergency medical services.[57,64]

AIRWAY

The simple basic procedures of head tilt, chin lift or jaw thrust remain the mainstay of airway management. Insertion of an oropharyngeal airway, correctly sized from the centre of the mouth to the angle of jaw, may be of use to aid simple airway control in the short term.

Tracheal intubation is the most effective method of securing the paediatric airway. Using a straight bladed laryngoscope and a plain plastic tracheal tube of the appropriate size (internal diameter (mm)=(age in years/4)+4) is a technique which requires a skill only developed by formal training and regular practice. Intubation must be achieved rapidly and accurately without prolonged delay to basic life support. Any attempt lasting longer than 30 s should be abandoned and the child's lungs reoxygenated before another attempt is made. Having achieved tracheal intubation the tube needs to be fixed carefully in place to prevent accidental removal or displacement.

The laryngeal mask airway has been assessed as an effective airway adjunct in adult resuscitation and is a technique that can be taught easily to doctors, nurses and paramedic staff.[2,20,21,59,75,89] Small-sized laryngeal masks are available for infants and children but their effectiveness in paediatric resuscitation has yet to be established. They are probably most significant where intubation is difficult or where the health care provider is not proficient in paediatric tracheal intubation.

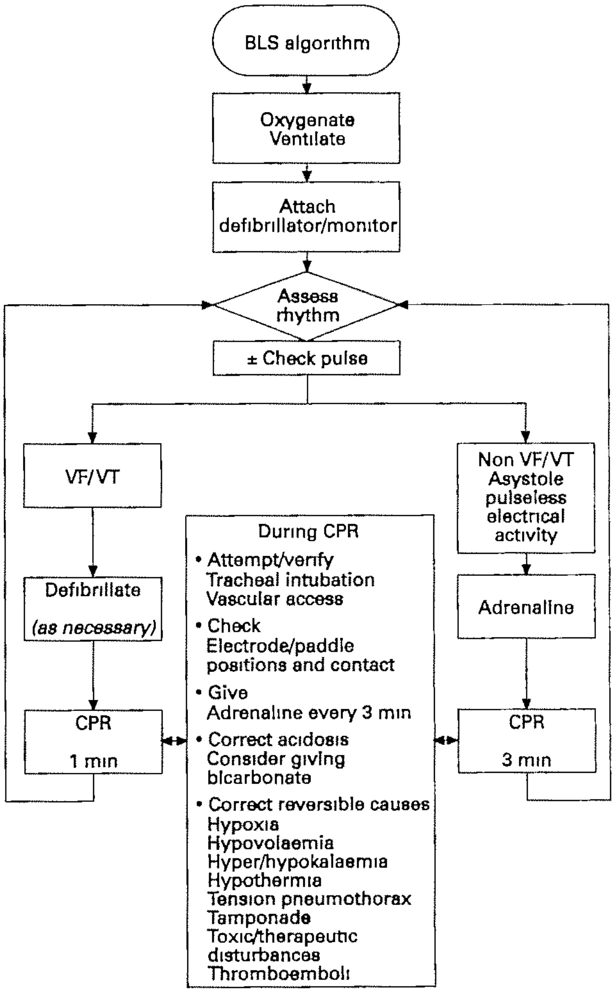

Figure 2 Algorithm for paediatric advanced life support. BLS=Basic life support.

OXYGENATION

Although expired air resuscitation provides some oxygenation, the sooner ventilation with high inspired oxygen concentrations can be established the better. Ventilation using a self-inflating bag–valve–mask with supplementary oxygen provides higher concentrations of inspired oxygen. Concentrations of up to 90% may be achieved if the self-inflating bag is fitted with an oxygen reservoir system. Face masks for use with a self-inflating bag should be of clear plastic so that the airway can be observed through the mask, and the circular design mask with a soft seal rim has been found to be most efficient, especially for the inexperienced operator.

Although many anaesthetists are experienced in the use of the Ayre's T-piece with the Jackson–Rees modification for paediatric ventilation, this system is not recommended for the less experienced and should not be part of the routine resuscitation equipment. Furthermore, this system requires a constant reliable gas delivery system to be functional and this may not always be immediately available. The self-inflating resuscitation bag can function independently and has the advantage that it can be operated safely and effectively by less experienced operators.

CIRCULATION

There are few procedures more fraught with difficulty in resuscitation than the establishment of venous access in an infant or small child during resuscitation. Yet circulatory access is of prime importance to effective advanced life support.[14,49] The i.v. or intraosseous routes for drug delivery are the preferred options. The site of venous access has to be balanced against the resuscitation skills and relative difficulty and risks of the technique. Experimental data have demonstrated that vascular access draining into the superior vena cava from either peripheral or central routes is preferable during resuscitation.[19,27,83] Drugs given via the inferior vena cava take longer to reach the heart.[27,83] Similarly, drugs administered centrally act more rapidly than those administered via the peripheral route.[5,27,41,53] However, access above the diaphragm is difficult and fraught with potential problems. Peripheral access, especially via veins in the lower limbs, is usually easier during resuscitation. Drugs administered via the peripheral route should be followed by a fluid flush to move them rapidly into the circulation.[28] Therefore, when judging the advantages of different access points and deciding which to select it must be remembered that accuracy, safety and speed are the key priorities.

Intraosseous access has gained popularity in the past few years. It is relatively easy to perform and generally safe. Resuscitation drugs and fluids administered by this route reach the heart in a time comparable with direct peripheral venous access.[3,70,85,102] Although originally recommended for children less than 6 yr of age, the intraosseous route has been used in older age groups and in adults during cardiac resuscitation.[35,102] When establishing intraosseous access it is important to recognize the criteria for successful entry into the bone marrow. There should be loss of resistance as the marrow cavity is entered, the needle should remain upright without support, bone marrow should be aspirated into a syringe and there should be free flow of drugs and fluid without subcutaneous infiltration around the entry point.[7,30,94] Marrow aspirates can be used for estimation of concentrations of haemoglobin, sodium, potassium, chloride and glucose.[101] Almost all drugs and infusions can be administered via the intraosseous route except bretylium tosylate,[80] but this drug is rarely administered to children. Complications of intraosseous cannulation include osteomyelitis, long bone fractures, extravasation of drugs subcutaneously and compartmental syndrome.[18,33,42,54,67,76,79,85,92]

The tracheal route of administration of drugs is preferred after the i.v. and intraosseous routes. It is best used where there has been, or is likely to be, a significant delay in establishing venous access and thus administration of drugs. Therefore, during resuscitation of the small infant or child it could be argued that the first important dose of adrenaline should be given by the tracheal route while venous access is being established.[38,56] There has been little research on the efficacy of drugs administered via the tracheal route in children. The optimal dose of drug, its volume and concentration have yet to be established.[48,61,77,81] Tracheal administration, despite its apparent simplicity, has some disadvantages, especially in the post-resuscitation period. Hypertension and tachycardia, neither of which are optimal in the post-arrest myocardium, have been reported and attributed to the depot storage effect of adrenaline which occurs in the lungs.[39,44,45,69,78] Severe hypertension may also be an underlying cause for poor cerebral outcome.[10]

Although direct intracardiac injection still has its advocates, it is now regarded as a last resort, only to be used when all other methods have failed.

TREATMENT ALGORITHMS

Administration of adrenaline plays a pivotal role in the advanced life support algorithms of paediatric resuscitation. Adrenaline is the drug of choice in any paediatric event as, by its alpha adrenergic action, it increases aortic diastolic filling pressure and thereby improves coronary perfusion.[52,71] Establishing venous access and ventilating with oxygen are the first steps in advanced life support and form the basis for the advanced treatment procedure. The algorithm then divides into two pathways according to the underlying cardiac rhythm—non-ventricular fibrillation (or tachycardia) or ventricular fibrillation (or tachycardia).

Non-ventricular fibrillation or tachycardia

Profound bradycardia or asystole is the most common rhythm associated with cardiac arrest in infants and children. Profound bradycardia (usually described as a pulse less than 1 beat s^{-1}) may precede asystole but in itself bradycardia does not produce adequate cardiac output in children.

Profound bradycardia should therefore be treated in the same way as asystole. Treatment is an initial dose of adrenaline 10 $\mu g\ kg^{-1}$ i.v. or by the intraosseous route (or 10 times this dose via a tracheal tube if venous access has not been established) (10 $\mu g\ kg^{-1}$ is 0.01 $mg\ kg^{-1}$ or 0.1 $ml\ kg^{-1}$ of a 1:10 000 solution). Recent studies in animals[9,13,36,85] and children[74] have suggested the benefit of a higher dose of adrenaline for the unresponsive asystolic child. Therefore, should the child not respond to the initial dose, another dose of 100 $\mu g\ kg^{-1}$ (0.1 $mg\ kg^{-1}$ or 0.1 $ml\ kg^{-1}$ of a 1:1000 solution) is recommended. Further studies have shown that if the child does not respond to this higher dose the eventual outcome is likely to be poor.[23,90,105] In reviewing the results of these studies, no children survived to discharge of those given more than two doses of adrenaline. The algorithm may therefore be self-limiting but there is not enough evidence at present to recommend limitation of the time course of resuscitation from non-ventricular fibrillation.

Where there is a cardiac rhythm but no cardiac output (electromechanical dissociation/pulseless electrical activity) it is also necessary to treat any of the underlying reversible causes of the arrest. Hypoxia, hypovolaemia, tension pneumothorax, cardiac tamponade, drug overdose, hypothermia and electrolyte imbalance are all treatable, and resuscitation attempts should not be abandoned until a reasonable attempt has been made to correct these potentially reversible causes of cardiac arrest.

Ventricular fibrillation and tachycardia

These rhythms, although common in adults, are relatively rare in infants and children. Although one study[32] reported an incidence of ventricular fibrillation of 23% in children, most other studies have reported an incidence of 0–10%.[25,3,57,68,98] None the less, the physician must always be aware of the occasional need to treat ventricular fibrillation in children by defibrillation.

The recommended sequence is to give two rapid defibrillatory shocks of 2 $J\ kg^{-1}$, followed by a single shock at 4 $J\ kg^{-1}$. All further defibrillation attempts should then be made at 4 $J\ kg^{-1}$ in a rapid repeated series of three shocks. After the first cycle of three defibrillation attempts adrenaline 10 $\mu g\ kg^{-1}$ should be given and another dose of 100 $\mu g\ kg^{-1}$ after the second cycle of three shocks and between all subsequent cycles. When ventricular fibrillation occurs in children there is often an underlying cause and correction of hypothermia, drug overdose (tricyclic antidepressant overdose) and electrolyte imbalance (hyperkalaemia) should be considered.

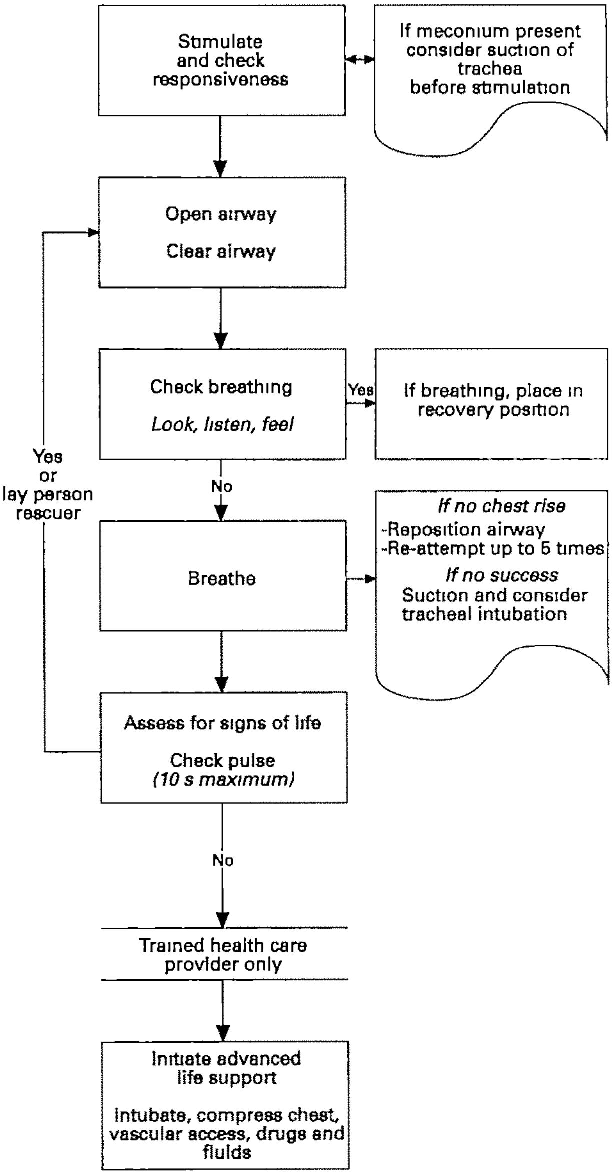
Resuscitation of the newborn (fig. 3)

Despite the fact that most newborn infants breathe spontaneously after delivery, it has been estimated that 900 000 infants per year worldwide could be saved from newborn asphyxia by the use of simple airway manoeuvres. Of the 5 million newborn deaths per year worldwide, 56% of which occur in "out-of-hospital births", 19% of these are caused by birth asphyxia. In the UK, newborn mortality is much lower but, with the increase in "out-of-hospital" deliveries, it is important that the birth attendant not only be fully conversant with obstetric problems but also be proficient in the techniques of resuscitation in the newborn.

The majority of newborn infants cry within a few minutes of birth and require little more than careful drying and wrapping in a warm towel to prevent heat loss. If the baby does not cry, it should be gently stimulated by more vigorous drying with a towel or flicking the soles of the feet. More vigorous stimulation is contraindicated and can be potentially dangerous.

The newborn baby's initial cry and subsequent efforts at breathing must be assessed carefully to ensure that they result in adequate and sustained oxygenation of the lungs. Gasping without additional efforts at breathing is usually considered inadequate. Abnormal or absent ventilatory patterns require immediate active intervention.

The sequence of resuscitation recommended for



Stimulate and check responsiveness
If meconium present consider suction of trachea before stimulation
Open airway
Clear airway
Check breathing
Look, listen, feel
Yes
If breathing, place in recovery position
Yes or lay person rescuer
No
Breathe
If no chest rise
-Reposition airway
-Re-attempt up to 5 times
If no success
Suction and consider tracheal intubation
Assess for signs of life
Check pulse
(10 s maximum)
No
Trained health care provider only
Initiate advanced life support
Intubate, compress chest, vascular access, drugs and fluids

Figure 3 Algorithm for resuscitation of the newborn.

the newborn follows the same *ABC* sequence as that described for the young infant. The emphasis in the newborn lies with *A* (airway) and *B* (breathing). If *C* (circulation) is needed then more advanced technical interventions, including the use of drugs, are probably required.

AIRWAY

The airway is formally opened by the head tilt, chin lift or jaw thrust manoeuvre. The resuscitator must ensure that the head and neck are not over-extended as this may kink and occlude the soft newborn trachea. Any secretions, mucus or blood should be removed carefully with a suction device but vigorous blind suction of the pharynx must be discouraged as it may induce apnoea and bradycardia.

BREATHING

If clearing the airway does not result in adequate breathing then the birth attendant must commence artificial ventilation as quickly as possible. It is important to recognize that the continued survival of any newborn rests in its ability to take the "first breath" and to continue to breathe. Without the first breath the lungs fail to expand or develop a functional residual capacity. Furthermore, the anatomical changes in the circulation, which in the fetus have enabled blood to bypass the lungs, persist.

In extreme circumstances, when no equipment is available, ventilation can be initiated by mouth-to-mouth and nose ventilation. Because the newborn baby is covered in maternal blood and body fluids associated with birth, this represents a significant health infection risk to the rescuer. Therefore, before commencing this form of expired air ventilation, the face and mouth of the infant should be carefully, but rapidly, cleaned. Ideally, and in most cases, the birth attendant should be equipped with a simple ventilation device, either a bag–valve–mask or an expired air T-tube. A circular mask with a soft seal edge is recommended as it has been found to be more effective, especially in the hands of the inexperienced rescuer. Ventilation rate should be 30–60 bpm and each breath delivered should cause the chest to rise visibly. Excessively high airway pressures must be avoided as they may damage the newborn lungs. Most devices now used for newborn resuscitation are fitted with a pressure limiting valve set at 30–40 cm H_2O. It should be remembered that the first breath may require a slightly higher inspiratory airway pressure to overcome the resistance of the fluid filled airways and the low compliance of the unexpanded lungs.

Continued failure to breathe signals the need for the resuscitator to intubate the trachea with a straight sided tracheal tube of appropriate size using a straight neonatal bladed laryngoscope. Tracheal intubation secures the airway and allows careful controlled ventilation with high concentrations of inspired oxygen. If, on attempting intubation, the trachea is seen to be filled with thick meconium, intubation should continue. Suction is then applied carefully to the tracheal tube as the tube is withdrawn slowly allowing removal of the thick meconium.

CIRCULATION

The newborn heart rate shortly after delivery should be greater than 100 beat min^{-1}. The pulse in the newborn is best assessed by palpating the base of the umbilical cord. Bradycardia should be treated initially by establishing effective ventilation and oxygenation of the lungs but, if there is not rapid recovery of the heart rate, techniques, now considered to be advanced, must be commenced.

Chest compressions in the newborn should be applied only by trained health care providers. If heart rate is less than 60 beat min^{-1} and not improving, chest compressions should be started. Chest compressions can be applied using the same method as for small infants or by applying two thumbs placed side by side over the sternum at the centre of an imaginary line joining the nipples, each hand circulating the child's chest. Compressions are carried out at a rate of 120 events per minute interposing one ventilation between every three chest compressions (a ratio of 3:1 for newborns).

If heart rate fails to respond to chest compressions accompanied by effective ventilation of the lungs with a high concentration of inspired oxygen, the umbilical cord should be cannulated with a 5-French gauge umbilical catheter.

There is still disagreement as to the first pharmacological intervention in advanced neonatal resuscitation.[15] Adrenaline is the favoured choice at a dose of 10 μg kg^{-1} (0.1 ml kg^{-1} of a 1 in 10 000 solution) flushed through the cannula with saline. Some authorities recommend an initial dose of sodium bicarbonate to reverse the acidosis present in the newborn but the dangers of infusing sodium bicarbonate[37 50] and the adverse effects of giving hyperosmolar fluids to neonates[29 93] must be considered carefully. If bicarbonate solution is administered it is given in a dose of 1–2 mmol kg^{-1} (2–4 ml of a 4.2% solution) over 2–3 min. It must be flushed carefully through the umbilical catheter so that it does not inactivate any drug administered subsequently.

Some infants require expansion of their circulating blood volume; 10–20 ml kg^{-1} of cross-matched blood or albumin usually establishes an effective circulation. If there is a history of opioid administration in the mother before delivery, this could be the cause of respiratory depression in the neonate. Naloxone 100 μg kg^{-1} should be given and the infant observed carefully to ensure that respiratory depression does not return when the effect of naloxone wears off. All newborn babies who require intervention beyond that of simple early ventilatory support for a short period of time must be admitted to a special care baby unit for observation, monitoring and continuation of care.

Conclusion

Paediatric life support is an essential part of the resuscitation cycle. To be effective, those practising paediatric resuscitation at basic or advanced levels need to be trained properly and practised in the skills of the procedure. Delay or hesitation in recognizing the need for or performing resuscitation can have disastrous consequences.

The recent publication of International Advisory Statements has simplified the approach to resuscitation by unifying the various national bodies, reviewing the published literature and recommending a single pathway described by the best available medical science. There is still much that is based on unproved theories but with the use of standardized reporting formats it is hoped that these will become fewer and the results of resuscitation will improve.

Drugs in modern resuscitation

R. VINCENT

Cardiopulmonary resuscitation addresses several life-threatening conditions, broadly classified by presenting cardiac rhythm into ventricular fibrillation (VF) (or pulseless ventricular tachycardia), asystole (with or without P waves) or electromechanical dissociation (EMD). Our greatest therapeutic success follows the correction of the underlying abnormality with minimum delay. Of crucial importance is early electrical defibrillation for patients in VF, airway management and ventilation for those with primary respiratory insufficiency and volume repletion for hypovolaemic EMD.

The role of drugs remains contentious. Animal models have provided data that sometime seem conflicting and are of limited applicability to human cardiopulmonary arrest. Prospective studies during clinical resuscitation are few and have raised doubts more often than provided confirmation of the use of agents that have been used hitherto on theoretical, retrospective or anecdotal evidence.

The use of drugs in modern resuscitation is directed at:

- improving organ perfusion during CPR
- facilitating electrical defibrillation
- preventing the recurrence of malignant ventricular arrhythmias
- increasing excitability and conduction, particularly in nodal tissue during profound bradycardia or asystole
- normalizing important metabolic derangements (including unwanted drug effects) contributing to, or resulting from, the arrest
- protecting the brain (and to a lesser extent the heart) from the effects of prolonged, intense hypoxia.

Physiology of cardiopulmonary arrest and resuscitation

The physiological state of a patient presenting with cardiopulmonary arrest depends on several factors: the precipitating pathology of the arrest, any additional disease processes, prior drug treatment and delay in the initiation of resuscitation. Cardiac arrest after a period of profound hypoxia may be associated with an established metabolic acidosis; prior respiratory obstruction or depression may have generated a respiratory acidosis with elevated P_{CO_2}. Pain in the pre-arrest period triggers a surge in autonomic activity encompassing both adrenergic and cholinergic effects.

Abrupt circulatory standstill, even without a prior biochemical disturbance, has several key metabolic consequences.

HYPOXIA

Cardiac arrest, after a brief period, leads to a steep decrease in arterial P_{O_2}. Moreover, a simultaneously advancing respiratory acidosis shifts the haemoglobin–oxygen dissociation curve adversely, reducing saturation for a given oxygen concentration. Mixed venous blood is severely desaturated as a consequence of arterial hypoxia and a dramatically slow capillary flow in spite of effective CPR.

ACIDOSIS

Acidosis arises from a combination of carbon dioxide retention and steady accumulation of the products of anaerobic metabolism. After the onset of VF, the pH in venous blood samples from the myocardium decreases from baseline to less than 6.8 in approximately 10 min[42]; acidosis in peripheral blood is recordable in a similar time even in the face of immediate CPR.[147] But, it is *tissue* acidosis that develops more rapidly and is the more sinister in its effects.

In the brain, nuclear magnetic resonance spectroscopy during cardiac arrest with external CPR shows a profound decrease in pH within 5–6 min, threatening tissue survival.[21] Tissue acidosis is also seen early in the heart[23] which, as in other cells, follows marked accumulation of carbon dioxide.[94] This change results in reduced myocardial contractility, reduced automaticity of pacemaker cells, a decreased threshold for ventricular fibrillation and opposition to the effects of catecholamines.[104 148] At intracellular concentrations of carbon dioxide greater than 63 kPa,

(*Br. J. Anaesth.* 1997; **79**: 188–197).

Key words
Heart, resuscitation. Complications, ventricular fibrillation. Complications, asystole. Acid–base equilibrium. Heart, antiarrhythmics.

RICHARD VINCENT, BSC, MD, FRCP, FESC, AKC, Department of Cardiology, Royal Sussex County Hospital, Brighton and Trafford Centre for Graduate Medical Education and Research, University of Sussex, Falmer.

resuscitation from mechanical arrest may not be possible.[94]

During CPR, mixed venous blood conveys to the lungs the acidic products of anaerobic metabolism giving rise to a pH of approximately 7.15.[144] It reflects the acid–base status of tissues more accurately than arterial blood which, through effective chest compression and ventilation, may be so cleared of carbon dioxide that its pH lies in the normal or even alkalotic range.[109 144]

CATECHOLAMINES

Cardiovascular collapse is accompanied by a substantial release of catecholamines from the adrenal medulla and adrenergic nerve terminals. Plasma concentrations of adrenaline, noradrenaline and dopamine increase rapidly after acute myocardial infarction[63 90 142] with concentrations that seem proportional to the extent of myocardial damage.[90 91] The highest concentrations of endogenous plasma catecholamines occur after cardiac arrest and CPR where concentrations of up to 50 times baseline have been recorded.[48 67 91 132] Deleterious effects may include hyperglycaemia, hypokalaemia, production of lactate and free fatty acids, and sensitization to arrhythmias. That exogenous catecholamines appear helpful in resuscitation in spite of these changes remains unexplained but suggests an inhibitory effect from the other metabolic derangements of cardiac arrest.[21]

OTHER CHANGES

A variety of other metabolic changes are precipitated by circulatory arrest. These include an increase in adrenal corticosteroids, ADH and blood sugar (with a decrease in insulin and tissue glucose use[97]), in addition to a range of haematological and protein responses that follow a state of shock.[141] An increase in the endogenous metabolite adenosine, which opposes the effects of catecholamines, has also been shown.[135]

HAEMODYNAMIC STATE

Circulatory collapse treated by CPR results in a highly abnormal haemodynamic state. Cardiac output reaches no more than one-third of normal,[27] probably less,[127] and circulation time is substantially slowed. Although perfusion is redistributed to the upper part of the body, particularly the brain and myocardium, animal models show that the calculated minimum required cerebral and myocardial blood flow (18 and 10 ml min^{-1}/100 g tissue, respectively[35 51 99 102 112]) are unlikely to be achieved during CPR without the use of vasopressor agents.[32 84 112]

The driving force, and limiting factor, for myocardial perfusion is aortic diastolic pressure. In animal models a pressure of 30–40 mm Hg is associated with improved survival.[29 103 115 146] At present, this seems best enhanced by pharmacological antagonism to the profound venous and arteriolar dilatation that results from the acidosis of cardiac arrest.[98]

Not surprisingly, the distribution volume and pharmacokinetics of most drugs are altered extensively during cardiac arrest and CPR,[116] and are influenced importantly by the route of administration.

Routes of administration

The routes chosen for drug administration during CPR represent a compromise between the practicality of access and their apparent efficacy to deliver drugs to the central circulation. Peripheral and central veins, and tracheal (endobronchial) administration are the most commonly used routes. The intraosseous route may be worthwhile in children[47] but intracardiac administration has now fallen from favour; other routes (femoral vein, intranasal) seem impractical.

PERIPHERAL VEINS

Drugs injected into the veins of the antecubital fossa during CPR reach a peak in the major systemic arteries at 1.5–3 min after injection.[15 45 82 118] Circulation time is shortened by up to 40%, however, if the bolus drug is flushed into the vein with 20 ml of diluent. This provides an effect similar to that of central venous injection.

The flushing solution now recommended is normal saline to avoid enhancing the metabolic disadvantage of 5% dextrose in worsening the progressive hyperglycaemia of circulatory arrest.[131]

CENTRAL VEINS

Compared with peripheral administration, the delivery of drugs by a central route achieves a faster drug appearance, higher peak concentration and a more potent pharmacological effect.[16 65 82] Kuhn and colleagues, in their classic experiments with indocyanine dye, showed a peak concentration in the femoral artery at 30 s compared with 90 s after peripheral administration[82]; in an animal model, lignocaine reached a concentration of 34.5 mg litre^{-1} after central compared with 22 mg litre^{-1} after peripheral injection[10] and even higher concentrations than this have been recorded in humans. Most workers agree that supra-diaphragmatic central venous administration is the most efficacious route for drug delivery during closed chest compression.[62 140 128]

But in a clinical cardiac arrest other practical issues are relevant. A central cannula requires interruption of CPR and may be hazardous in patients after recent thrombolysis. Even with normal blood clotting, central venous insertion is associated with a complication rate of 1–14%,[41 140] and placement may not be 100% successful.[36 44] Hence a wide-bore antecubital venous cannula through which bolus drugs are flushed with normal saline may best suit drug delivery in practice, at least in the early phase of most resuscitation attempts.[3 4 43]

TRACHEAL

The lung capillary surface area of 70 m^2 offers a potential route for drug administration during CPR, especially as tracheal intubation occurs early in an arrest and may be easier to achieve in practice than i.v. cannulation.[78] One study estimated the time saved by this approach to be 4 min.[133] Adrenaline, atropine, lignocaine, naloxone and bretylium can be given by this route,[56,100,119,134] although absorption may be via the tracheal or bronchial mucosa rather than the alveolar capillary network.

In animals, tracheal administration of adrenaline mimics its effect intravenously[124]; in humans, vasoconstriction traps adrenaline in the lungs to produce a lower plasma concentration and delayed peak[56,131] but a longer duration of action than after i.v. administration.[125] Atropine also has a slower time-course of action by this route.[134]

The dose and dilution of drugs given by the tracheal route remain controversial. Although up to 10 times the i.v. dose may be necessary to achieve the same effect as i.v. administration,[120] current European recommendations[3] are to use twice the usual i.v. dose for tracheal delivery during clinical cardiac arrest. There is conflicting evidence on the optimal diluent in relation to the effects of normal saline and dextrose in both drug absorption and the inevitable transient decrease in therapeutic oxygenation and pH[107] seen after their use.

The efficacy of tracheal delivery is influenced strongly by technique.[93] Currently recommended practice is to inject the drug diluted in 10 ml of normal saline via a catheter that extends to just beyond the end of the tracheal tube, but tracheal administration is now seen as a route to be used only if i.v. access is delayed.

INTRACARDIAC

Intracardiac adrenaline has been proposed since the turn of the century,[29] and drug delivery by this route has often focused on other pressor agents.[64] But the technique of injection into the right ventricle by the sub-xiphoid route requires considerable expertise and may not be successful, often delivering the drug to an extra-cardiac site. Transection of the left anterior descending coronary artery can occur with a precordial, left parasternal route. Intracardiac delivery is now seen as a last resort.

Catecholamines and other vasopressors

Adrenaline is undoubtedly effective in improving the haemodynamic state of the patient during resuscitation. Cerebral and myocardial blood flow is enhanced by preventing arterial collapse and by augmenting aortic diastolic pressure by an increase in peripheral resistance.[29,76,98,111,115,146] These effects are mediated primarily through stimulation of alpha$_1$ and alpha$_2$ receptors. Alpha$_1$ receptors are found near the outer wall of peripheral vessels, respond primarily to neuronally released noradrenaline[18] and may be down-regulated or desensitized by the metabolic milieu of a cardiac arrest. Alpha$_2$ receptors are located near the vascular lumen, respond primarily to circulating catecholamines and may play a more an important role in regulating vasomotor tone during resuscitation.[21]

The contribution of the additional effect of adrenaline at beta$_1$ and beta$_2$ receptors is unclear. Beta$_1$ effects appear to have no advantage in restoring a spontaneous circulation from VF, asystole or EMD; moreover, adrenaline at high doses may increase myocardial oxygen consumption and may predispose to later arrhythmias.[17,31,74] Although it is difficult to show benefit from beta$_2$ stimulation in restoring spontaneous circulation,[87] this action has been shown to dilate the cerebral microvasculature[40] and improve cerebral perfusion.[20]

The optimum dose of adrenaline has been a matter of continuing interest and debate fuelled by conflicting evidence.[16,19,20,52,61,78,92] Animal studies have indicated repeatedly the benefit of doses of adrenaline 3–10 times higher in a weight-adjusted bolus than is currently used in humans (approximately 15 mg kg^{-1}). A dose-dependent improvement in regional myocardial and cerebral blood flow has been recorded during closed chest compression in animals over the range 0.02–2.0 mg kg^{-1}[16,19,20,61] and similar data have now been found during human cardiac arrest.[52,113] More recent prospective, controlled clinical studies in adults[17,22,138] showed an improvement in the return of spontaneous circulation with higher doses, but no improvement in survival to hospital discharge. One study[88] showed preferential benefit in patients with EMD or asystole when treated with 5 mg rather than 1 mg of adrenaline but, perhaps because of a type II error, the result did not reach clinical significance.

Vasopressor agents other than adrenaline seem theoretically attractive in providing powerful alpha adrenergic stimulation while avoiding potentially deleterious beta effects. There are few reports on the comparative benefit of noradrenaline, although its action on alpha$_1$ and alpha$_2$ receptors allows it to mimic adrenaline in its ability to improve myocardial and cerebral blood flow. In one study by Lindner, Ahnfeld and Grunert,[87] the effect of 1 mg doses of noradrenaline and adrenaline were compared; noradrenaline resulted in a greater than two-fold increase in the return of spontaneous circulation but had no effect on survival to hospital discharge.

In contrast, methoxamine and phenylephrine (predominantly alpha stimulants) are less effective in promoting coronary and cerebral blood flow[16,19,20] even at doses that result in an equivalent increase in aortic diastolic pressure and a rate of return of spontaneous cardiac output. This phenomenon has been attributed to the lack of effect of these agents on alpha$_2$ receptors[21] or to the "missing" effect of beta$_2$ stimulation which may contribute to a successful outcome.

The nearly pure beta agonist, isoprenaline, has a predictably adverse effect on the circulation during cardiac arrest. Beta$_2$-mediated vasodilatation causes a decrease in mean arterial pressure reducing coronary perfusion while its beta$_1$ effects threaten an increase in myocardial oxygen requirements. The sole indication for isoprenaline is that of short-term chronotropic support of a patient en route to electrical pacing for haemodynamically significant bradycardia.[4,43] A brittle response may be seen even with careful titration of the i.v. infusion, and hypokalaemia and ventricular arrhythmias may be induced.

There is no mandate from the data currently available to suggest a policy for catecholamine administration during cardiac arrest other than that embodied in the European and American guidelines.[3,13]

Atropine

Atropine blocks cholinergic muscarinic receptors and isolates the heart from the effect of the parasympathetic nervous system, particularly in nodal tissue. As a result, the automaticity and conduction of both sinoatrial and atrioventricular nodes are enhanced.

Atropine is most effective when a haemodynamically significant bradycardia results from high vagal tone (pain, vomiting, facial cold or trauma), global hypoxia or sensitization of nodal tissue to the effect of the vagus as a result of ischaemia. Its effect in asystole or EMD caused by widespread myocardial damage is negligible. In a few settings, a small number of asystolic patients have shown short-term benefit, but no survivors have been recorded attributed solely to the use of atropine.

Used as an agent for peri-arrest bradycardias, the dose is best balanced against its effect,[2] bearing in mind that (i) 0.5 mg may exert an agonist action with a resulting bradycardia and susceptibility to VF,[30] and (ii) 3 mg produce a fully vagolytic effect.[110] The adverse effects of atropine (delirium, tachycardia, coma, hot skin, ataxia, urinary retention, blurred vision and pupillary muscle dilation), however, are usually regarded as benign.

Antiarrhythmic agents

Electrical defibrillation remains the key treatment in most cases of successful adult resuscitation, but in this setting antiarrhythmic drugs have three potential uses:

- to terminate a malignant ventricular arrhythmia
- to facilitate electrical defibrillation
- to prevent the recurrence of VT or VF.

Antiarrhythmic drugs are commonly classified according to their cellular mechanism of action—the Vaughan–Williams classification (table 1). Few have properties limited solely to a single cellular effect and some (particularly bretylium and amiodarone) have clear actions in two or three classes.

Table 1 The Vaughan–Williams classification of antiarrhythmic drugs

Class of action	Examples
Class I: Blockade of sodium channels:	
A Moderate prolongation of conduction and repolarization:	Quinidine Procainamide Disopyramide
B. Minimal effect on conduction and repolarization:	Lignocaine Mexiletine
C. Marked prolongation of conduction:	Flecainide Propafenone
Class II: Blockade of β adrenergic receptors.	Propranolol Atenolol
Class III: Prolongation of repolarization:	Amiodarone Bretylium Sotalol
Class IV: Blockade of calcium channels:	Verapamil Diltiazem

Agents of classes I, II and III are effective in the prevention of ventricular arrhythmias, but their use in practice is often limited by their unwanted actions: myocardial depression, proarrhythmic action and non-cardiac side effects. Moreover, their ability to suppress benign arrhythmias while exerting little influence on the incidence of unheralded VF or mortality have also diminished enthusiasm for their use. The agents in centre stage of modern resuscitation are lignocaine, bretylium and amiodarone, with supporting appearances by other class I and class III agents.

LIGNOCAINE

Lignocaine is a class IB agent which depresses excitability by blocking sodium channels without extending action potential duration. In animal models it also has an antifibrillatory action, although this requires higher doses than those necessary to suppress ventricular ectopic beats.[5,25,145]

Lignocaine suppresses impulse formation in the sinus node.[89] It has little effect on AV nodal conduction but may impede conduction below the bundle of His. Conveniently, lignocaine produces only weak myocardial depression,[28] has little effect on vasomotor tone and does not reduce coronary perfusion pressure during resuscitation. Its proarrhythmic action is also weak and although its CNS side effects include restlessness and convulsion, these are seen rarely.

Lignocaine is of undoubted value in the treatment of ventricular extrasystoles and tachycardia, particularly in acute myocardial infarction. Its ability to prevent ventricular fibrillation in this context has also been demonstrated in several small studies[95,58] and in a larger prospective study by Koster and Dunning[80]; however, there is no convincing proof of an improvement in overall mortality as a result.[59] Two explanations have been offered: a higher occurrence of subsequent asystole that results from the use of this drug[142] and failure to use experimental conditions that would best show benefit in this regard.[24]

The contribution of lignocaine during an arrest to aid resuscitation from refractory VF remains contentious. Animal models have shown that it causes a marked increase in defibrillation threshold (increasing the energy required for cardioversion),[9,33,38,66] but data from limited human experiments are sparse.[24] Small-scale studies taken together have produced equivocal results.[57,106] Where success has occurred, lignocaine may have acted by preventing the immediate recurrence of VF rather than by facilitating the effect of the DC shock.[24,106]

Whether lignocaine results in an improved outcome from cardiac arrest in sustained VF was explored recently[58] in a retrospective observational study over a 12-yr period of 1212 cases treated outside hospital in Goteberg. This resulted in a comparison of 185 patients who had received lignocaine with 105 who had not. In the lignocaine group, 45% showed a return of spontaneous circulation compared with 25% in the group who had not received lignocaine ($P<0.001$). Comparable values for survival to reach hospital (38% *vs* 18%) were also significantly different ($P<0.05$). However, there was no difference in the rate of hospital discharge between the two groups (14% *vs* 8%; ns). Although treatment with lignocaine appeared to be an independent predictor for the return of spontaneous circulation and hospital admission, patients in the lignocaine group also received adrenaline and were attended by a nurse, both of which were rare in the non-lignocaine group. The results of controlled prospective studies of lignocaine and alternative antifibrillatory drugs are still needed.

BRETYLIUM

Introduced initially as an antihypertensive agent with adrenergic neurone blocking properties, bretylium was shown first to have important antifibrillatory actions in 1965.[85] As a class III agent it increases myocardial stability, elevating the threshold for VF and rendering more uniform the action potential duration between ischaemic and non-ischaemic tissue.[5 25]

Bretylium may lower the threshold for defibrillation[26 34] and should therefore aid recovery from VF. Not all investigations have reported this effect, however,[66 77] and little difference has been found between bretylium and lignocaine in small clinical studies.[77 106] The theoretical benefit of bretylium on defibrillation threshold may be outweighed by a subsequent action in producing EMD and post-arrest hypotension.[46] Bretylium appeared better than placebo during pre-hospital arrest[105] but the data were retrospective and uncontrolled. Prospective studies for this agent are mandatory.

AMIODARONE

First launched as a coronary vasodilator, the anti-arrhythmic properties of amiodarone were characterized first in 1970.[70 136] Its broad spectrum of activity and its favourable effect on myocardial contraction make it an attractive agent. In common with bretylium, amiodarone is a potassium channel blocker which lowers the defibrillation threshold. It also has a powerful antifibrillatory action.[114] Its effect in lengthening action potential duration places it in class III of the Vaughan–Williams classification but it also inhibits sodium-dependent depolarization giving it additional class I activity. Furthermore, it exhibits a degree of non-competitive beta blockade.[117]

Amiodarone has a weak depressant effect on the SA node and on AV nodal conduction. Its mild, and usually transient, negative inotropic effect appears restricted to rapid i.v. administration. Its peripheral vasodilatation, however, could theoretically oppose the beneficial action of pressor agents in supporting the circulation of the collapsed patient.

The efficacy of amiodarone for the treatment of malignant ventricular arrhythmia is well documented,[81 101] and its beneficial effects for secondary prevention in patients with acute myocardial infarction, congestive failure and primary ventricular arrhythmias have been explored extensively, generally with encouraging results. But the value of amiodarone during cardiac arrest has received little attention[149] and its inclusion in the resuscitation armamentarium is confined to the area of peri-arrest arrhythmias.[2]

Alkalizing agents

At the time when procedures for resuscitation became routine clinical practice, i.v. administration of sodium bicarbonate seemed a logical step to counteract the tissue acidosis found in cardiac arrest. In the mid 1980s this view was challenged. The hypothesis introduced by Weil and colleagues[54 144] was that carbon dioxide elimination was limited more by poor tissue perfusion than alveolar hypoventilation; also, the extensive production of carbon dioxide that follows i.v. administration of sodium bicarbonate would re-accumulate in the tissues themselves further reducing intracellular pH and adversely affecting outcome. Several key points of this argument have been challenged recently.[21]

First, although inadequate perfusion in an arrest limits carbon dioxide elimination, correctly performed CPR, supported by the vasopressor effect of adrenaline, remains effective and is one of the mainstays of the control of acid–base balance during resuscitation.

Second, i.v. administration of bicarbonate may not persistently increase venous carbon dioxide during CPR. Doubt about the validity of the results of previous experiments, both in humans[1 144] and animals,[50 69] have been voiced by Brown and colleagues[21] on the basis of experimental design; it is also possible that this phenomenon, if real, is transitory over a matter of only a few minutes.

Third, a major argument against the use of bicarbonate during CPR is that it worsens intracellular acidosis.[70] The pivotal study on which this theory rests is that of Bernyi, Wolk and Killip[11] whose experimental dogs received bicarbonate 10 mmol kg^{-1} over a 20-min period of resuscitation. As this represents a dose of 700 mmol in humans, the clinical relevance of this experiment must be open to doubt. Additional evidence has been published that both supports[71 137] and refutes[69 126 130] the adverse effect of sodium bicarbonate on cytoplasmic pH, particularly in myocardial cells.[86]

Finally, what evidence is there that bicarbonate alters the clinical progress of resuscitation? Both positive[72 123 129] and negative[50 55 68 130] results have been reported from experiments in animals. But no prospective controlled studies have been performed to demonstrate the effect of sodium bicarbonate on the outcome of cardiac arrest in humans. Retrospective studies suffer from the association of bicarbonate administration with arrests that were inevitably prolonged and therefore unlikely to be successful.

For brief resuscitation procedures, sodium bicarbonate is probably irrelevant having neither a good nor a bad effect,[12 14 55] but its use in prolonged (>10 min) arrests needs careful evaluation. Administration of a buffer to correct lactic acidosis in a hypoxic state has been shown to decrease cardiac output by reducing left ventricular contractility, a

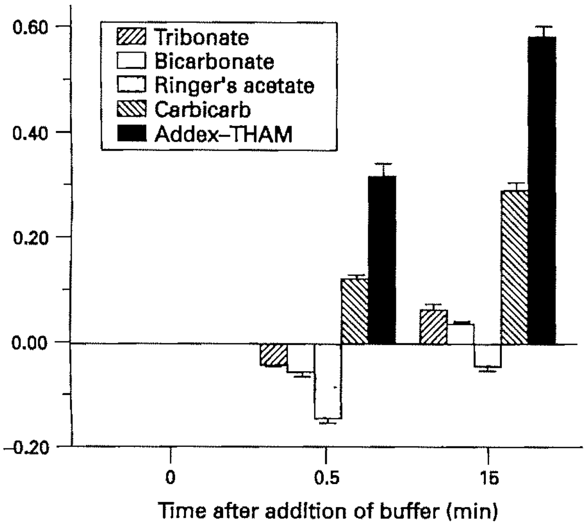

Figure 1 Changes in cytoplasmic pH (pH_i) after addition of Tribonate, sodium bicarbonate, Ringer's acetate, Carbicarb or Addex-THAM (mean, SEM) to suspended rat myocardial cells during hypoxic conditions (from Li, Wiklund and Bjerneroth,[86] with permission).

change associated with an increase in lactic acid production and a reduction in blood pH.[7,53] A large prospective human study of buffer therapy in cardiac arrest[37] also failed to show benefit. But advantages have been reported in relation to the reduction in defibrillation threshold,[72] higher rates of return of spontaneous circulation,[123] reduced incidence of recurrent VF,[72] improved neurological outcome[83,123] and increased rates of hospital discharge.[39] Benefit appears to follow a titrated dose of bicarbonate to replenish the depleted HCO_3 ion and the concurrent use of adrenaline,[13] the effect of which is enhanced by pH correction.[96] (In the absence of adrenaline, hypertonic buffers limit coronary perfusion pressure.) Buffer agents other than bicarbonate have been explored chiefly in animal models. In an experiment by Li, Wiklund and Bjerneroth,[86] bicarbonate, Tris buffer (trometamol), Tris buffer mixture (Tribonate), Ringer's lactate and Carbicarb were tested in a cellular model of hypoxic cardiac arrest. Figure 1 shows the resulting change in pH from the initial acidotic cytoplasmic pH of 6.85. The most favourable agent was judged to be Tribonate which, in larger doses, caused almost complete correction of intracellular acidosis without overcompensation. No clinical benefit, however, has yet emerged from the use of this agent.[37]

At this stage, to abandon bicarbonate therapy completely seems unwise but its use appears best confined to the later stages of cardiac arrest where effective ventilation and chest compression have been established for some while, where adrenaline has been used to support vascular collapse according to existing procedures and where the dose can be titrated in a manner that allows balanced repletion of the bicarbonate ion.

Calcium and magnesium

CALCIUM

Although ionic calcium is intimately involved in impulse formation and excitation–contraction coupling, human studies have shown that its contribution as a pharmacological agent to recovery from any form of cardiac arrest is negligible or adverse.[139]

The accumulation of intracellular calcium that results form profound ischaemia promotes myocardial damage and impaired neurological outcome. Exogenous calcium may amplify these effects[49,150] and is therefore indicated only if the patient presents in the unusual state of drug overdose with calcium channel blocking agents.[3,43]

MAGNESIUM

Magnesium mirrors the action of increased extracellular potassium in stabilizing the myocardial cell membrane.[8] In contrast, decreased intracellular magnesium (often resulting from the diuretic treatment that depletes potassium) renders the myocardium more excitable and thus more prone to ventricular arrhythmias.[60,122]

Exogenous magnesium has been shown to suppress ventricular extrasystoles not only in a depleted state but also when plasma and tissue concentrations are normal.[121] An additional "pharmacological" action is therefore postulated. The place of magnesium in cardiac arrest is uncertain[6] and untested but the use of 10 ml of a 50% solution of magnesium sulphate is unlikely to be harmful when the patient is known to have prior hypokalaemia.

Conclusion and future directions

Patients most likely to recover from cardiac arrest are those who collapse because of VF and who receive successful electrical defibrillation within 90 s. The chances of survival are poor if three shocks in rapid succession, together with basic life support, fail to restore a spontaneous output; any pharmacotherapy at this stage represents a last "desperate effort to resuscitate".[108]

"Most drug regimens in resuscitation, even those in use for many years, are based on animal evidence, indirect evidence and common sense. They are rarely based on sound clinical experiments because of practical and legal constraints. No drug used in resuscitation has benefit established unequivocally according to the principles of 'evidence-based medicine'. Moreover, no drug whether it be epinephrine, lidocaine, or bicarbonate, which are the most widely used can be given without risks; the possibility of adverse outcome because of overdose is a real possibility, but equally difficult to prove."[79]

This slightly pessimistic quote should not detract from the attempts that have been made (with increasing scientific rigour) to set the understanding and treatment of cardiac arrest on a secure scientific base. Prospective clinical studies of most of the "accepted" agents are warranted in addition to the development of more tailored drugs that could reverse the rapidly degenerating metabolic milieu of circulatory standstill. Agents to enhance tissue perfusion during CPR, to retard hypoxic cellular necrosis buying time before definitive treatment can be given and to facilitate electrical defibrillation are the highest priorities for research.[21]

But the difficulties of research in human resuscitation are substantial. Operational, ethical and scientific hurdles are the most challenging of all in this setting. Yet such research is mandatory to secure the most effective regimens for resuscitating collapsed patients; these hurdles should not be allowed to prevent the inclusion of sufficient numbers of patients to obtain statistically and clinically significant results. Meanwhile, adherence to the consensus recommendations of the major bodies with an interest in resuscitation, particularly with regard to the agents discussed, is advised.[3 43 75]

Peri-arrest arrhythmias

D. CHAMBERLAIN

Many victims of cardiac arrest suffer the event in the context of a critical illness complicated by malignant rhythm disorders. Moreover, almost all patients who are resuscitated initially from a cardiac arrest have a subsequent course characterized by bradyarrhythmias or tachyarrhythmias which are likely to need treatment to restore an adequate circulatory state or to prevent further collapse. Thus competence in the management of cardiac arrest *per se* is an incomplete skill for those—usually not cardiologists—who aspire to practice advanced cardiac life support. They should also be able to recognize and treat cardiac arrhythmias that are of their nature potentially malignant or that may become life threatening in some clinical contexts—notably in the aftermath of cardiac arrest. The term "peri-arrest arrhythmias" encompasses all rhythm disorders in these situations. Guidelines on the management of peri-arrest arrhythmias published by the European Resuscitation Council[1] and subsequently revised[2] offer advice at three levels: treatment modalities that might reasonably be expected from any individual treating a cardiac arrest; when expert help should ideally be sought; and advanced management strategies that might be considered when expert help is not immediately available.

Peri-arrest arrhythmias that may lead to or complicate cardiac arrest are considered under three broad headings: bradycardias and two types of tachycardias. The designation of bradycardia usually relates to disorders of heart rhythm with a rate of less than 60 beat min^{-1}. But this can usefully be extended beyond the conventional definition to include the concept of "relative bradycardia", applicable to heart rates that are greater than 60 beat min^{-1} yet inappropriately slow within the clinical context. A heart rate, for example, of 70 beat min^{-1} may be the modal value in healthy adults yet abnormally slow to a degree that calls for treatment in the presence of cardiogenic shock. Tachyarrhythmias are conventionally divided into those that arise within the ventricle (ventricular tachycardia) or above (supraventricular tachycardia). This classification has merit based on principles of pathological substrate, aetiology, treatment, prognosis and usage, but is presented in the guidelines in a modified form to take account of diagnostic difficulties.[10] Ventricular tachycardia characteristically has a broad QRS complex reflecting delayed depolarization through abnormal pathways, but a minority of tachycardias arising below the AV node may show complexes with a width that lies within the normal range. Supraventricular tachycardia, on the other hand, characteristically shows a narrow QRS complex that is often very similar in shape to that of the usual beats, but two common exceptions cause confusion. First, normal conduction is not possible at very high rates, in particular the right bundle may fail under these conditions so that the pattern of depolarization may be abnormal with a wide QRS of a right bundle branch block pattern even in rhythm disorders arising in the atrium or within the AV node. This so-called rate-related aberration is more common in the presence of heart disease. Second, a pattern of depolarization that is abnormally prolonged during an individual's normal rhythm is at least as prolonged during tachycardia. Thus the width of the QRS complex during tachycardia does not reliably distinguish ventricular from supraventricular origin. Many other features may indicate the true origin of a tachycardia, but accurate classification may be difficult and may not always be possible from the surface electrocardiogram. The guidelines therefore make no assumption that the origin of a tachycardia has been defined accurately. Recommendations for treatment are based instead on the simple classification of narrow complex tachycardias (which are usually supraventricular and may be treated as such with acceptable safety) and broad complex tachycardias (which should be assumed to be ventricular for purposes of treatment as this is the safer strategy).

Separate algorithms are available for bradycardia, narrow complex tachycardia and broad complex tachycardia. The principles of treatment are similar to those used in any clinical context, but the following points should be noted:

- The algorithms are designated specifically for the peri-arrest situation but they cannot encompass all situations that may arise.
- The algorithms are intended for physicians (or those working under the direction of a physician)

(*Br. J. Anaesth.* 1997; **79**: 198–202).

Heart, arrhythmia. Complications, arrhythmia. Complications, cardiac arrest.

DOUGLAS CHAMBERLAIN, CBE, MD, DSC (HON), FRCP, FRCA, FESC, FACC, Royal Sussex County Hospital, Eastern Road, Brighton BN2 5BE.

who do not regard themselves as experts in arrhythmia management. Therefore, management strategies that are complex or potentially dangerous when used inappropriately are omitted as far as possible.

- The algorithms have to be broadly applicable in all European countries notwithstanding different traditions of antiarrhythmic therapy. Some drugs have been omitted as options because they are not universally available, and alternatives have been offered where it is necessary to do so.
- The algorithms assume that oxygen is being administered and i.v. access is available.
- The arrows indicating progression from one treatment to the next are to be followed only if the arrhythmia is still present.
- All antiarrhythmic strategies (physical manoeuvres,[22] drugs[13] or electrical treatment[7]) can be proarrhythmic. Deterioration may therefore occur as a result of treatment rather than as a consequence of lack of effect. Moreover, the use of multiple antiarrhythmic drugs or high doses of a single drug can cause myocardial depression and hypotension. How far sequential treatments should be pressed in the face of these risks may be a matter for careful clinical judgment.
- The algorithms provide doses based on average body weight and may need adjustment, particularly for small individuals. Doses expressed in mg/kg body weight are judged inappropriate for use in emergency situations because calculations are more likely than usual to introduce error.

Bradycardia

The algorithm for bradycardia is shown in figure 1. The apparent complexity is misleading because the management principles are simple and may be summarized thus: if there is a risk of asystole, pace as soon as possible; *if there is no perceived risk of asystole but the haemodynamic state of the patient is poor, give atropine and pace only if this is ineffective; if there is no perceived risk of asystole and the patient is not compromised haemodynamically to an important degree then only observation is required.* The algorithm, however, provides more information around this framework.

The first and most important decision relates to whether or not there is a perceived risk of asystole. Observed performance of the heart rhythm provides a guide. A history of asystole is a self-evident risk factor in this regard. A pause longer than 3 s also causes concern because reliable subsidiary pacemakers should provide escape beats within a briefer interval. Other criteria in the presence of heart block are based on indications that the site of block is either in the region of the AV node itself (in which case reliable and adequate subsidiary pacemaker tissue should still be available to drive the ventricle) or alternatively below the AV node (in which case any subsidiary pacemakers may be irregular, are likely to be unduly slow and are certainly unreliable). Thus complete heart block with a narrow QRS complex is not in itself an indication for treatment. Conversely, an abnormally wide QRS complex with complete atrioventricular block implies that the subsidiary pacemaker cannot conduct through the usual pathways and may therefore be below the division of the bundle of His into its bundle branches (unless there is pre-existing bundle branch block or the rare phenomenon of bradycardia-dependent bundle branch block). Mobitz type II AV block which is the last of the criteria requires more explanation. During the evolution of AV block a phase usually occurs when some beats are conducted and some are not. This is known as second degree block but there are two types: for a "benign" block in the region of the AV node, intermittent failure of conduction is characterized by dropped beats in Wenckebach periods (also known as Mobitz I block); alternatively, when the failure is within the bundle branch system, the dropped beats occur unpredictably: there is no "warning" PR prolongation. Another marker of problems within the bundle branch system is also present and very obvious. Intermittent failure of a depolarization wave to conduct through the bundle branch system occurs only if one of the bundle branches has previously failed, so that even the conducted beats show bundle branch block of some type. Mobitz type II second degree AV block is therefore characterized by wide QRS complexes in the conducted beats, together with intermittent abrupt failure of conduction. The risk is clear: one bundle branch has already failed and the other is indicating it may do so with no reliable pacemaker tissue available at a lower level.

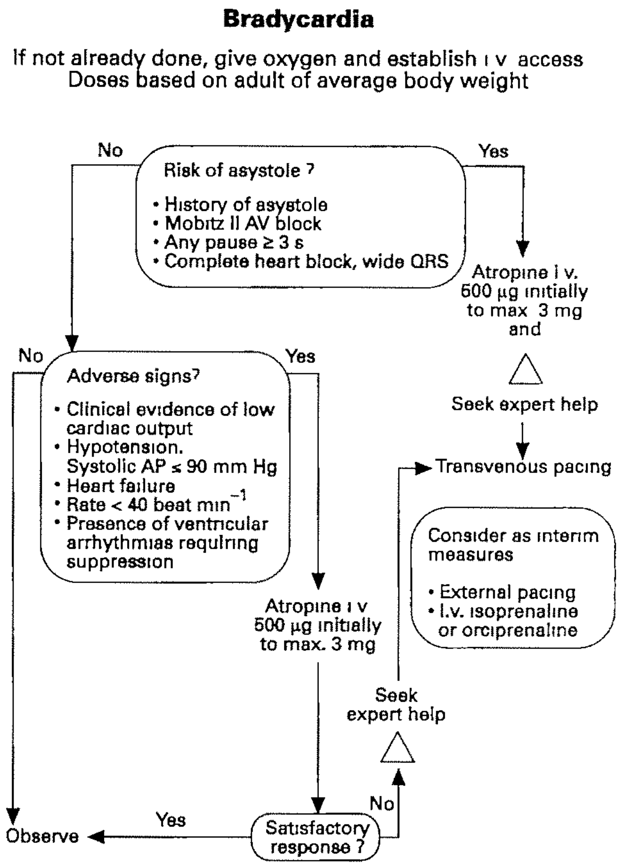

Figure 1 Algorithm for bradycardia

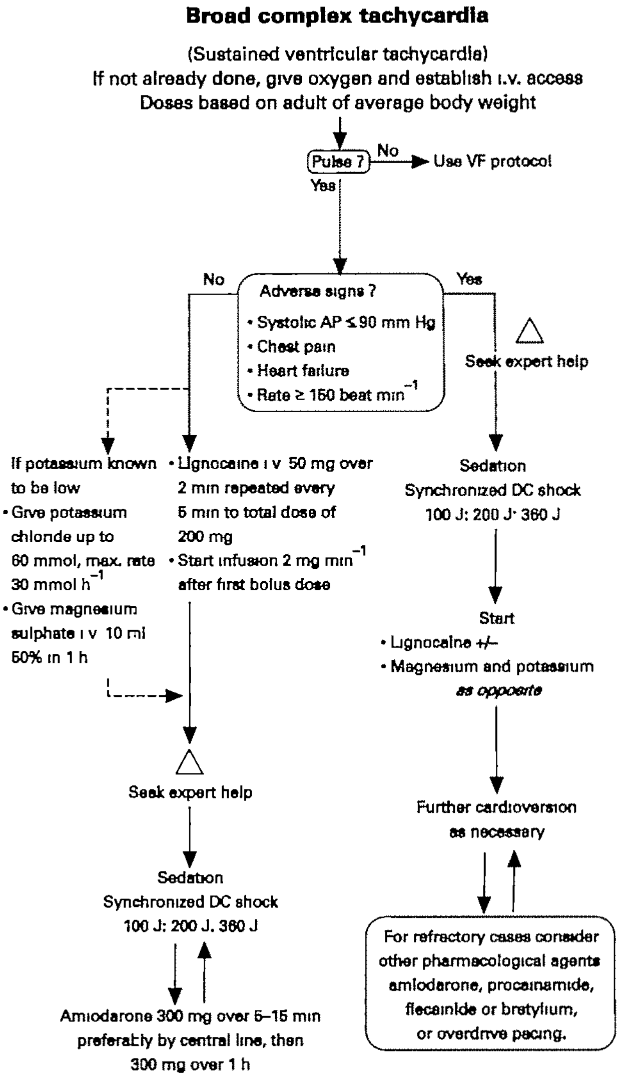
If any of the warning signs are present indicating that asystole is a definite risk, transvenous pacing should be established as soon as possible. The responder who is not an expert in arrhythmia management may wish to do no more than establish i.v. access and give atropine in a dose of 500 μg to 3 mg while waiting for expert help from others with the necessary specific skills. In this situation, however, the use of atropine is frequently unsuccessful. When a patients's condition is critical, external pacing[8] with appropriate sedation should be considered: it is simple to implement provided the equipment is available. The judicious use of isoprenaline is an alternative strategy, with the usual starting dose of 1 μg min^{-1} which may be increased 10-fold or more in a desperate situation, always having regard to the risk of precipitating or worsening ventricular arrhythmias and increasing myocardial oxygen consumption. Orciprenaline is an alternative chronotropic catecholamine used in some countries.

The second decision for those not at immediate risk of asystole is based on the presence or absence of adverse haemodynamic signs. Clinical evidence of low cardiac output, hypotension (arterial pressure less than 90 mm Hg) and overt heart failure are self-evident factors. Heart rate less than 40 beat min^{-1} is included because complications are likely to occur even if such a slow rhythm is tolerated temporarily. The last of the criteria relate to prognostically or haemodynamically important ventricular arrhythmias—either complex forms of ventricular extrasystoles or non-sustained runs of ventricular tachycardia—which occur frequently with or as a complication of an underlying bradycardia. These are best treated by increasing the underlying rate. If an antiarrhythmic is used in this setting, bradycardia is likely to become worse and thus increase the risk from ventricular arrhythmia. In the presence of any of the five adverse haemodynamic signs, atropine should be administered, starting with an initial i.v. dose of 500 μg repeated to a maximum of 3 mg which provides virtually complete vagal blockade.[6] This usually produces a satisfactory response at least temporarily, but if necessary expert help would be needed with a view to transvenous pacing. Only rarely does a patient's haemodynamic condition justify the use of external pacing or the risky chronotropic catecholamines while awaiting definitive treatment.

Bradycardias that do not carry a risk of asystole and are not likely to have important adverse haemodynamic effects require no treatment. Indeed, in the context of myocardial infarction they may have a favourable influence by limiting myocardial oxygen requirement

Broad complex tachycardia

The algorithm for broad complex tachycardia is shown in figure 2 and can be summarized into three possible treatment policies: *if there is no pulse as a result of the arrhythmia the condition should be treated as cardiac arrest using the ventricular fibrillation/ventricular tachycardia algorithm for cardiac arrest; if there is a pulse but inadequate perfusion, cardioversion is required as soon as possible. If there is a broad complex tachycardia without adverse haemodynamic disturbance, routine antiarrhythmic therapy should be used, with cardioversion only if this fails.* The algorithm provides further information around this framework.



Broad complex tachycardia
(Sustained ventricular tachycardia)
If not already done, give oxygen and establish i.v. access
Doses based on adult of average body weight
Pulse ?
No
Use VF protocol
Yes
No
Adverse signs ?
• Systolic AP ≤ 90 mm Hg
• Chest pain
• Heart failure
• Rate ≥ 150 beat min⁻¹
Yes
Seek expert help
If potassium known to be low
• Give potassium chloride up to 60 mmol, max. rate 30 mmol h⁻¹
• Give magnesium sulphate i v 10 ml 50% in 1 h
• Lignocaine i v 50 mg over 2 min repeated every 5 min to total dose of 200 mg
• Start infusion 2 mg min⁻¹ after first bolus dose
Sedation
Synchronized DC shock
100 J: 200 J: 360 J
Start
• Lignocaine +/-
• Magnesium and potassium as opposite
Seek expert help
Further cardioversion as necessary
Sedation
Synchronized DC shock
100 J: 200 J. 360 J
Amiodarone 300 mg over 5–15 min preferably by central line, then 300 mg over 1 h
For refractory cases consider other pharmacological agents amiodarone, procainamide, flecainide or bretylium, or overdrive pacing.

Figure 2 Algorithm for broad complex tachycardia.

The first decision relates to the presence or absence of a palpable pulse, with the implication that a victim with an absent pulse is also unconscious and clinically in cardiac arrest. When this is not the case, a second decision is reached, relating to adverse signs. These include hypotension (arterial pressure less than 90 mm Hg) and heart failure as for bradycardia, but also the presence of chest pain which might either be the result or the cause of the rhythm disorder, and any rate faster than 150 beat min^{-1} because this is likely to presage problems even if it does not do so at the onset. If any of these signs are present the situation must be regarded as an emergency and expert help should be sought even before sedation and synchronized shock are considered. Energies less than 100 J should not be used because they may have proarrhythmic effects, so attempts at restoration of a more satisfactory rhythm should use sequentially 100 J, 200 J and 360 J. In the unlikely event of cardioversion being unsuccessful, the algorithm recommends the use of lignocaine

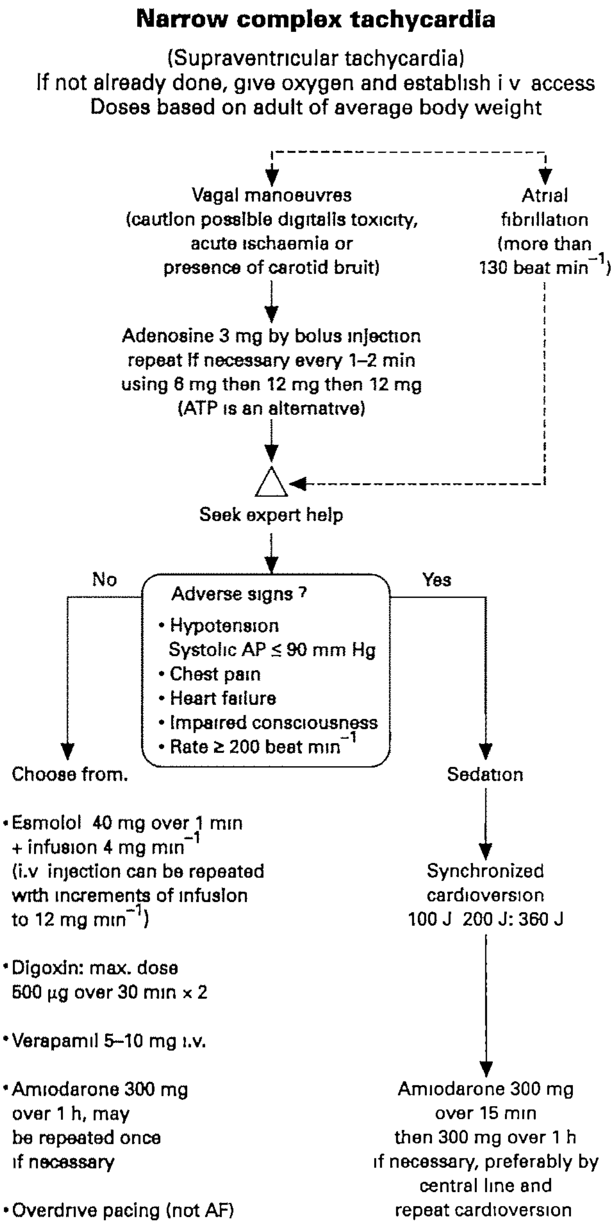
50 mg over 2 min, repeated every 5 min to a total dose of 200 mg with an infusion of 2 mg min^{-1} set up after the first bolus dose. If the concentration of potassium is known to be less than 3.6 mmol litre^{-1}, especially in the presence of recent infarction,[15] potassium chloride should be given in a dose of up to 60 mmol, but the maximum infusion rate should never exceed 30 mmol h^{-1}. Magnesium concentrations should be assumed to be deficient in the presence of hypokalaemia, and this is corrected by magnesium sulphate i.v.[24] in a dose of 10 ml of a 50% solution over 1 h. If the arrhythmia persists, further shocks should be attempted when lignocaine 200 mg has been administered: in the presence of adverse signs it is inappropriate to delay electrical treatment for full correction of electrolyte deficiencies. Other drugs that may be used if cardioversion is not successful after lignocaine include amiodarone,[16] procainamide,[14] flecainide,[20] propafenone[17] or bretylium[3]: any one of these may sometimes reverse the arrhythmia or act as successful adjuncts to cardioversion. Clearly every drug that is administered unsuccessfully adds to myocardial depression, and polypharmacy can be justified only in desperate situations. Overdrive pacing[25] is a method of controlling ventricular tachycardia without a persistent adverse effect on heart function, but it calls for considerable expertise in arrhythmia management.

For broad complex tachycardia that is not causing appreciable adverse signs, the lignocaine regimen should be started before any attempts at cardioversion, and hypokalaemia is treated concurrently. If this is not successful expert help should be sought. The management is then likely to consist of synchronized shock (100 J, 200 J, 360 J), with amiodarone as the recommended adjunctive therapy if shock alone is unsuccessful or if the arrhythmia is recurrent.[21] The time for completion of the amiodarone infusion is more than 1 h, but assessment of urgency on clinical grounds will determine how long should elapse before further shocks are given after the first set of three have been unsuccessful.

Narrow complex tachycardia

This is almost always supraventricular tachycardia, and as a peri-arrest arrhythmia is less frequent and somewhat less hazardous. Supraventricular tachycardias are, however, a recognized trigger for malignant ventricular arrhythmias in some clinical contexts,[12] including myocardial ischaemia, and atrial fibrillation is a relatively common peri-arrest arrhythmia.

The algorithm shown in figure 3 can be summarized as follows: *for regular supraventricular tachycardias, vagal manoeuvres or adenosine may be tried first, but if these are not successful in the presence of adverse signs the first strategy is cardioversion; without adverse signs there is a choice of routine antiarrhythmic agents that include a short-acting beta-blocker, digoxin, verapamil and amiodarone.* The algorithm adds further details to this outline.



Narrow complex tachycardia
(Supraventricular tachycardia)
If not already done, give oxygen and establish i v access
Doses based on adult of average body weight
Vagal manoeuvres
(caution possible digitalis toxicity, acute ischaemia or presence of carotid bruit)
Atrial fibrillation
(more than 130 beat min⁻¹)
Adenosine 3 mg by bolus injection repeat if necessary every 1–2 min using 6 mg then 12 mg then 12 mg
(ATP is an alternative)
Seek expert help
No
Yes
Adverse signs ?
• Hypotension
Systolic AP ≤ 90 mm Hg
• Chest pain
• Heart failure
• Impaired consciousness
• Rate ≥ 200 beat min⁻¹
Choose from.
• Esmolol 40 mg over 1 min + infusion 4 mg min⁻¹ (i.v injection can be repeated with increments of infusion to 12 mg min⁻¹)
• Digoxin: max. dose 500 μg over 30 min x 2
• Verapamil 5–10 mg i.v.
• Amiodarone 300 mg over 1 h, may be repeated once if necessary
• Overdrive pacing (not AF)
Sedation
Synchronized cardioversion
100 J 200 J: 360 J
Amiodarone 300 mg over 15 min then 300 mg over 1 h if necessary, preferably by central line and repeat cardioversion

Figure 3 Algorithm for narrow complex tachycardia

Vagal manoeuvres must be considered first, but they may not always be appropriate in peri-arrest situations: they are dangerous in the presence of acute ischaemia, with digitalis toxicity or in elderly patients, especially in those with a carotid bruit because of vulnerability to plaque rupture with cardiovascular complications.[4] Adenosine, however, is a comparatively safe treatment,[5] using rapid bolus administration at a starting dose of 3 mg, repeating every 1–2 min with increments to 6 mg, then 12 mg and, if necessary, a final second dose of 12 mg. Ideally adenosine is given into a central vein because its half-life is measured in seconds and a more peripheral injection may be inactivated before it reaches the coronary circulation. The injection should, in any case, be given as rapidly as possible. Even with central injections administered rapidly, severe circulatory impairment that slows the circulation may prevent an adequate concentration ever reaching the coronary circulation. If these simple treatments are unsuccessful, or if atrial fibrillation is identified, then expert help should be sought.

The factors that indicate adverse signs are similar as for broad complex tachycardia: hypotension (systolic pressure less than 90 mm Hg), heart failure and chest pain. But the list in this case includes impaired consciousness (which may occur without full cardiac arrest) or a rate of more than 200 beat min^{-1} (rather than 150 beat min^{-1} for broad complex tachycardia). In the presence of any of these signs the treatment should be by synchronized cardioversion using sequentially 100 J, 200 J and 360 J as necessary after appropriate sedation. If this fails amiodarone should be administered at an initial dose of 300 mg by central i.v. injection over 15 min, followed by 300 mg over 1 h. Spontaneous reversion may occur during the amiodarone infusion but otherwise repeat cardioversion should be attempted. If the need to reverse the arrhythmia is pressing, one or more shocks may be given during the amiodarone infusion. For refractory or recurrent atrial fibrillation, the slowing induced by amiodarone may relieve any haemodynamic compromise and be judged a satisfactory outcome. Occasionally controlled atrial fibrillation may be the most stable rhythm that can be achieved and may then be preferable to other recurrent supraventricular rhythms.

In the absence of adverse signs there is no one recommended "best buy". One reasonable choice may be esmolol[23] which is a short-acting beta blocker and can be used in a dose of 40 mg over 1 min (which may be repeated) with an infusion starting at 4 mg min^{-1} and increments as necessary to 12 mg min^{-1}. Digoxin may have a role either for the control of atrial fibrillation or for terminating some regular supraventricular tachycardias. The recommended dose is 500 μg over 30 min which can be repeated once. Verapamil is highly effective for narrow complex tachycardia in other situations but should be used with great caution in the peri-arrest situation, and is best reserved for the expert because there are circumstances in which its use is hazardous. These include arrhythmias associated with Wolff–Parkinson–White syndrome,[11] tachycardias that are ventricular in origin,[19] and some of the supraventricular arrhythmias of childhood.[18] The dose is 5–10 mg i.v. The dangers of interaction between verapamil and beta blocking agents is of particular concern if the drugs are used i.v.[9] Amiodarone may also be used, and in this context the appropriate dose is 300 mg over 1 h, repeated once if necessary. Overdrive pacing can also be effective but requires considerable expertise. It is not appropriate in the presence of atrial fibrillation.

Fibrillation and defibrillation of the heart

L. L. BOSSAERT

Fibrillation is chaos[38 47 83 88 107]

Fibrillation of the atrium or ventricle of the heart is a result of chaotic electrical activity of the heart chambers, resulting in loss of coordinated myocardial contraction. Fibrillation of the atrium is characterized by loss of coordinated atrial contraction and by irregular conduction of this chaotic electrical activity through the A-V conduction system to the ventricles, leading to an irregular pumping pattern of the ventricles. Fibrillation of the ventricles is characterized by loss of coordinated ventricular contraction, leading to an immediate loss of pump function of the heart and causing cessation of blood flow and oxygen supply to the vital organs of the body. Loss of oxygen supply to the brain causes brain damage and eventually brain death after only a few minutes. This represents the pathophysiological substrate of sudden cardiac death (SCD).

The mechanism of initiation of ventricular fibrillation (VF) consists of the simultaneous presence of an arrhythmogenic substrate and a trigger. The substrate is usually an area of ischaemic myocardium or an ischaemic border zone surrounding an infarcted area. The substrate becomes increasingly vulnerable (decreased fibrillation threshold) by increased concentrations of circulating catecholamines, sympathetic imbalance, metabolic abnormalities, proarrhythmogenicity of drugs, and hyper- and hypothermia. The final trigger is usually an early ventricular premature ectopic beat (VPB). Coexistence of abnormal initiation of ventricular beats (increased excitability of the substrate, latent pacemaker activity) and abnormal propagation of the impulse (bradycardia, intraventricular conduction blocks, re-entry phenomena) generate chaotic electric activity in the presence of a lowered fibrillation threshold. An increase or marked slowing of heart rate are predisposing factors in the initiation of VF. When this chaos is present in a critical mass of ventricular myocardium, fibrillation invades the whole ventricle causing VF.

In the initiation of VF, a so-called "R-on-T" extrasystole is an important factor; late cycle ectopic ventricular tachycardia and idioventricular rhythm initiate VF less frequently.

Aetiology and epidemiology of VF

Primary VF (in the absence of shock or cardiac failure) occurs in the first 5–10 min after the onset of coronary occlusion and is usually induced by an early R-on-T VPB and only rarely by degeneration of ventricular tachycardia. The success rate for resuscitation of patients in the first minute of primary VF is probably 90–95%.[2 21 75]

Data on Holter monitoring have demonstrated that VF waves initially have a large amplitude of >0.2 mV and a median frequency of ±200–300 bpm. Progressively, rate and amplitude decrease and after approximately 12–15 min, fibrillation waves fade to become a flat isoelectric line.[13 53 64]

Secondary VF occurs in the presence of shock or cardiac failure and is caused by a variety of mechanisms, including dilatation, stretching, metabolic disorders, sympathetic overactivity and proarrhythmogenicity of drugs. Secondary VF has a far lower prognosis for successful resuscitation, with less than 30% success rate.

Ischaemic heart disease (IHD) is by far the principal cause of VF. More than 30% of all patients with acute myocardial infarction die from VF within the first 2 h after onset of symptoms. The majority of patients presenting with SCD caused by VF are those at risk of IHD (i.e. middle-aged men with other signs and symptoms of IHD). However, SCD caused by VF is not infrequently the first, and lethal, symptom of IHD.

Ischaemia and reperfusion are associated with life-threatening arrhythmias, but only 20% of SCD victims have an acute myocardial infarction. Therefore, transient ischaemia and reperfusion rather than infarction have major roles in triggering the arrhythmias leading to SCD.[39 91]

Other causes of SCD induced by VF include diseases of the heart (reperfusion, heart failure, congenital heart disease, cardiomyopathy, valvular, infiltrative and infectious disorders), transient autonomic and neurohumeral factors, toxic and proarrhythmic effects of drugs, hypothermia, electrolyte and metabolic disorders, hypoxia, hypotension and electric shock. In young subjects

Key words
Heart, resuscitation. Heart, arrhythmia, fibrillation. Equipment, defibrillators. Complications, cardiac arrest.

LEO L. BOSSAERT, University of Antwerp UIA, Universiteitsplein 1, b-2610, Antwerp, Belgium.

(age <40 yr) cardiomyopathy and toxic substances are more important aetiologies than IHD.

Epidemiological investigation (European Monica registry) showed that the incidence of SCD caused by VF was approximately 1 per 1000 inhabitants per year. The incidence is higher in Northern countries and lower in Mediterranean countries. This lower incidence of IHD is believed to correlate with a different nutritional profile (the "French paradox").[20 97]

In common with other symptoms of IHD, the time of onset of VF has a circadian distribution pattern with a relative high risk during the day and the highest peak in the first 3 h after awakening. This time variation is believed to correlate with the degree of sympathetic instability and related biochemical variations.[7 71 96]

VF and the chain of survival

Survival after pre-hospital cardiac arrest is more likely when activation of the emergency medical services (EMS) system, basic cardiopulmonary resuscitation (CPR), defibrillation and advanced care occur as rapidly as possible. Implementation of these various elements of CPR in the treatment of cardiac arrest can be described best by the concept of "chain of survival". This concept illustrates that failure or weakness of any one of these links is associated with poor results. The concept of chain of survival describes each link in the EMS continuum that is needed for survival in cardiac arrest.[5 30 72]

- The first link in the chain of survival, "early access", is essential to bring trained persons and appropriate equipment quickly to the patient, includes recognition of the collapse, decision to call, calling and dispatch, and is strengthened by public education and availability of an efficient emergency communication system (including a unique simple telephone number for medical emergencies).
- The importance of the second link, "early CPR", by the first person witnessing the arrest (lay person or bystander health care worker) has been well documented. Bystander CPR can maintain the heart in VF for approximately 10–12 min longer. Basic CPR can sustain life until arrival of trained personnel with equipment and is therefore a bridge to defibrillation.
- The most crucial link is "early defibrillation". Initially, pre-hospital defibrillation was performed only by medical and paramedical staff, but recently newer and reliable technology has allowed the defibrillator to be used by first-line technician ambulance personnel. This strategy is of greatest value as long as the preceding links of the chain of survival do not fail. In systems where access time is excessively long, the results of an early defibrillation programme may be disappointing.
- The fourth link, "early advanced life support", implies early intervention of a well-trained and equipped team, working with specially equipped ambulances or rapid intervention vehicles. These teams consist of paramedics (in the USA, UK and Scandinavia) or trained ambulancemen, doctors and/or nurses (in most European countries).

VF and defibrillation

In the event of VF, electrical defibrillation is the only effective method of terminating the rhythm disturbance and restoring a perfusing cardiac rhythm. Landmark investigators include Zoll and colleagues,[112] Dahl and colleagues[34] and Pantridge, Adgey and Webb.[86] The success of electrical defibrillation is dependent on time and the metabolic state of the myocardium. The chances of successful defibrillation decrease rapidly over time, at a rate of more than 5% per minute. After a few minutes, the amplitude and frequency of the VF waveform decreases and after approximately 15 min degenerates into asystole, probably because of depletion of myocardial high energy phosphate reserves. The presence of asystole usually indicates that the time since collapse has been prolonged.[16 17 22 25 60 93 102]

MECHANISM OF DEFIBRILLATION

External defibrillation of the heart involves delivering an adequate electrical current flow through the heart, via electrodes applied to the chest wall, causing simultaneous depolarization of all myocardial cells that are at that moment fully refractory. Defibrillators consist of a power source (battery, AC source), voltage selector, AC–DC converter, capacitor and electrodes.[11 15 35 46] The output energy of the defibrillator is usually expressed in energy, where:

$$\text{energy (J)} = \text{power (W)} \times \text{duration (s)}$$

$$\text{power (W)} = \text{potential (V)} \times \text{current (A)}$$

$$\text{current (A)} = \text{potential (V)/resistance or impedance } (\Omega).$$

The output waveform of most conventional external defibrillators is half sinusoidal (damped Edmark waveform). The optimum duration of the power wave is 4–12 ms.

After defibrillation, myocardial contraction is re-established within minutes, but initially cardiac output may be extremely low, especially after prolonged VF, and continues to increase over minutes or even hours. This phenomenon has been described as the post-countershock pulseless rhythm or post-countershock myocardial depression.

Inspired by the work of Russian investigators and by the experience of implanted automatic defibrillators, the use of biphasic or triphasic waveforms has been advocated. Indeed, post-countershock dysfunction of the myocardium appears to depend on shock waveform. The defibrillation threshold seems to be lower using biphasic waveforms and causes less myocardial dysfunction with implantable defibrillators. Others have suggested that the biphasic waveform may reduce the defibrillation threshold by prolonging refractoriness which may protect ventricular cells from refibrillation wavefronts. The clinical relevance of biphasic waveform defibrillation at different energy levels is being investigated.[12 49 109]

TRANSTHORACIC IMPEDANCE: THRESHOLD AND ENERGY REQUIREMENTS

Not all cases of VF can be defibrillated by an external shock. The minimum shock strength capable of abolishing fibrillation is defined as the defibrillation threshold. The defibrillation threshold is influenced by anatomical variations in heart size, ventricular filling and lung volumes, and electrical variables such as defibrillation waveform and metabolic state, and biochemical and physiological differences in temperature, tissue pH and $P\text{O}_2$, extracellular potassium concentration, ischaemia and drugs. The energy requirement for defibrillation increases with the duration of fibrillation. The sum of these variables can be responsible for a five-fold difference in threshold as time elapses.[37 59 77]

In VF/tachycardia, defibrillation is accomplished by passage of sufficient electrical current through the heart to depolarize a critical mass of myocardium. The amount of current flowing through the heart depends on the energy of the shock and transthoracic impedance. During transthoracic defibrillation in humans, as little as 4% of the delivered transthoracic current traverses the heart because parallel pathways (thoracic cage, lungs) divert the current away from the heart.[33 74]

Transthoracic impedance depends on many factors: time to defibrillation; electrode size, contact, pressure, and distance from the heart; previous shocks; and ventilatory phase. The success of defibrillation depends not only on threshold but also on probability.

Defibrillation at too high energy levels can be proarrhythmic and cause functional and morphological damage to the myocardium. Shocks below the defibrillation threshold are ineffective and harmful because they may re-initiate VF by stimulating parts of the myocardium during a vulnerable period.[82 95 108]

Prospective clinical investigations have demonstrated that the success of defibrillation and subsequent hospital discharge rates were almost identical in patients receiving an initial shock of 175 or 320 J. Therefore, the energy selected for the first shock is a compromise between probability of success and risk of damage.[58 66 101] Based on this scientific evidence, the following guideline has been accepted widely for defibrillating an adult presenting with VF: first shock—200 J; second shock—200–300 J; subsequent shocks ≤360 J.

In children, a weight-related initial energy of $2\ \text{J kg}^{-1}$ is recommended.[50]

The average human transthoracic impedance is 70–80 Ω, but can occasionally be as high as 150 Ω and as low as 15 Ω. The energy for the first shock can be predicted and adjusted based on automatic measurement of impedance, and inappropriate low energies can be avoided in patients with high impedances.[67] This facility is already available in modern equipment

INFLUENCE OF DRUGS ON FIBRILLATION AND DEFIBRILLATION THRESHOLDS

Intervention studies have demonstrated that some routinely used drugs are proarrhythmic, serving only to aggravate the situation.[8 41 45 51 52 54 61 65 68 70 73 81 85 89 90 98 100] The pharmacological profiles of bretylium, amiodarone and beta-blocking drugs are probably superior to other commonly used antiarrhythmics in the treatment of VF refractory to countershock (table 1). Bretylium and lignocaine increase the fibrillation threshold significantly. However, lignocaine also increases the defibrillation threshold whereas bretylium does not. Lignocaine in association with acidosis produces a further increase in the energy required; respiratory alkalosis causes a reduction in energy required to defibrillate successfully. Administration of lignocaine during myocardial reperfusion in CABG allows defibrillation with fewer DC shocks of lower energy and current. Bretylium lowers the defibrillation threshold in dogs and facilitates conversion of hypothermia-induced VF. However, deleterious effects of bretylium on haemodynamic recovery from VF have occasionally been reported.

Table 1 Pharmacological profiles of antiarrhythmic drugs

Drug	Fibrillation threshold	Defibrillation threshold	Proarrhythmogenicity
Quinidine	++	+++	+
Procainamide	++	0	+
Encainide	++	+++	+
Flecainide	++	+++	+
Lignocaine	++	+	+
Bretylium	++	−	+
Amiodarone	++	−	0/+
Verapamil	+	++	0
Diltiazem	+	++	0
Nifedipine	+	0	0
Adrenergic agents	−	0	+
Beta-blockers	++	+	0
Sotalol	+	−	+

The effect of other antiarrhythmic drugs is less clear (table 1): procainamide has no effect on defibrillation energy requirements. Flecainide significantly increases the defibrillation threshold and has adverse proarrhythmic and haemodynamic effects in dogs. Propafenone reduces energy requirements for defibrillation in pigs.

The calcium channel blocking drugs, diltiazem and verapamil, increase the defibrillation threshold, whereas nifedipine and nisoldipine do not.

Adrenaline has no effect and propranolol increases the defibrillation threshold. Beta stimulation decreased the defibrillation threshold significantly in dogs, an effect that was blocked by propranolol. Sotalol (DL and D) decreased defibrillation energy requirements.

Excessive administration of magnesium may increase the defibrillation threshold.

PRACTICAL CONSIDERATIONS

Paddle size, shape and position

Electrode pad size is an important determinant of transthoracic current flow during external countershock. Larger self-adhesive electrocardiogram/defibrillator pads are associated with a lower transthoracic impedance and improved defibrillation success rates with low energy shocks. The optimum electrode size is ±13 cm in diameter in adults, 8–10 cm in children and 4.5–5 cm in infants.[10 36] There has been no attempt to standardize the physical characteristics of adhesive pads for automated external defibrillators.

Paddle position influences current flow through the myocardium. One electrode should be placed below the outer half of the right clavicle and the other just outside the usual position of the cardiac apex (V4–5 position). Anterior–posterior (one paddle over the precordium and the other on the back just behind the heart) electrode placement may be recommended in patients with implanted defibrillators or pacemakers. The influence of polarity on the defibrillation threshold is negligible.[103]

Disposable coupling pads are as effective as electrode paste.[11] Jelly is probably less satisfactory as it tends to be spread across the chest wall during resuscitative efforts: the shock then arcs across the chest wall, failing to reach the heart in adequate strength.

Before performing external defibrillation, all nitro patches and ointments should be removed from the chest wall.[110]

External defibrillation and pacemakers

Pacemaker problems reported during external defibrillation include transient malfunctions of pacing, capture and sensing. Although modern pacemakers are less likely to be disturbed by external defibrillation, an increase in pacemaker threshold has been described. With implanted pacemakers, anterior–posterior electrode or paddle placement maintaining a distance of 12–15 cm from the pacemaker module is recommended. Pacing functions should be checked immediately in patients who have been defibrillated.[69 80 113]

Technical problems

In a review of more than 2100 technical reports related to defibrillator problems, some failures were attributable to component malfunctions, but errors in operator use and defibrillator care and maintenance accounted for the majority of defibrillator failures. Where defibrillators are used relatively frequently, such as in ambulances, emergency departments, intensive and coronary care units, operating theatres and catheterization laboratories, it is recommended that the operational state of the equipment is assessed every day using appropriate checklists.[29] Inadequate training and re-training increase the chances of operator errors at the critical moment.

Resuscitation algorithm for VF

Based on the available scientific knowledge, a universal algorithm for the advanced life support (ALS) management of VF patients has been proposed by the International Liaison Committee on Resuscitation (ILCOR) (fig. 1). This committee includes representatives from the European Resuscitation Council, American Heart Association, Canadian Heart and Stroke Foundation, Australian Resuscitation Council and Southern African Resuscitation Council.[13 44 94]

After confirmation of cardiac arrest, a precordial thump should be given immediately and the defibrillator pads applied. The diagnosis of VF should be followed immediately by three electric shocks of 200, 200–360 J, without interposed CPR. After the initial three shocks, the airway should be secured and i.v. access achieved, if these manoeuvres have not already been performed. At this stage adrenaline 1 mg i.v. should be given (2.5 mg if given by tracheal tube), and 10 sequences of five chest compressions: one ventilation should be given.

The next shocks should be given as quickly as possible and the interval between the third and next (fourth) shock should not exceed 2 min: the more rapid a coordinated rhythm is restored, the better the prospects of long-term success. In patients whose trachea is intubated, the next shock should be given immediately after the 10 CPR cycles have been completed and adrenaline was given, and tracheal intubation should be aborted temporarily if unsuccessful after approximately 30 s.

The fourth shock forms the beginning of a new sequence of three shocks. Additional doses of adrenaline 1 mg may be given at less than 2-min intervals (fig. 1).

Automated external defibrillator (AED)

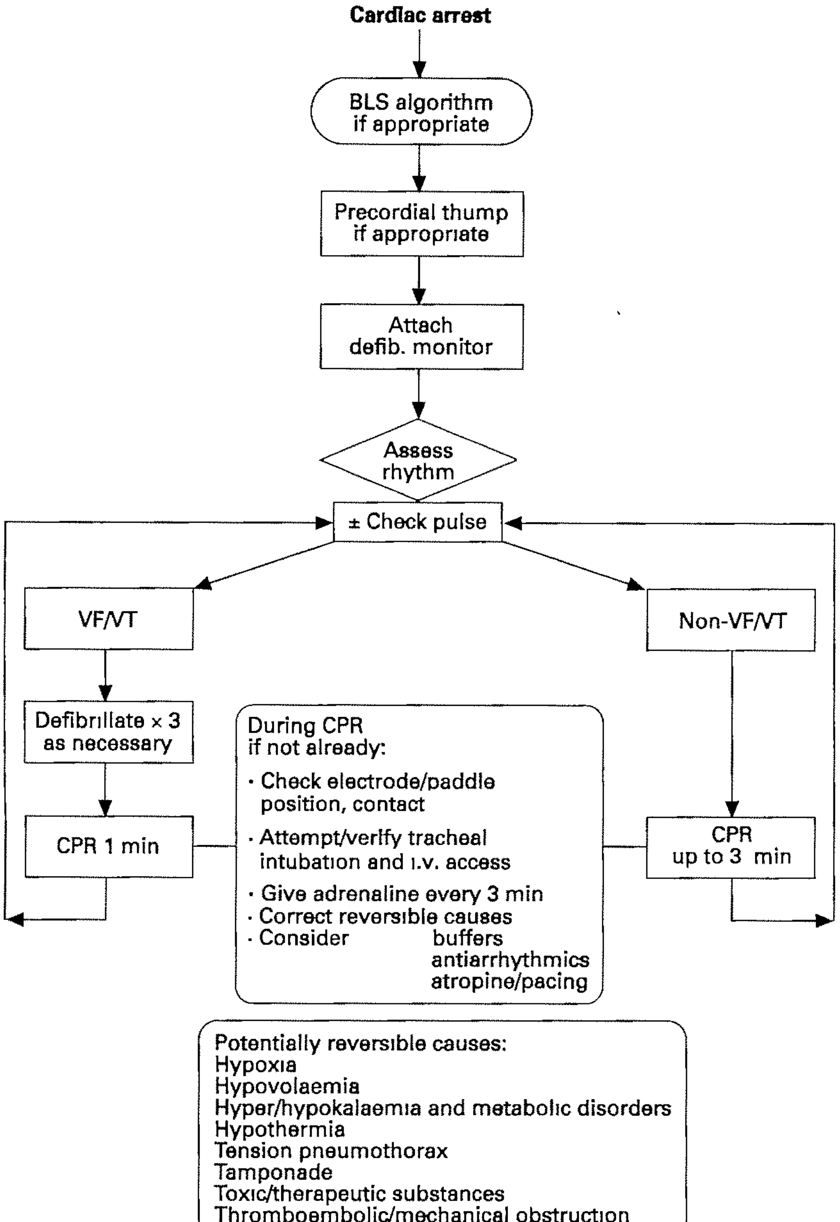
The most frequent initial rhythm in SCD is VF. The most effective treatment for VF is electrical defibrillation; the probability of successful defibrillation diminishes rapidly over time and VF tends to convert to asystole within a few minutes. The rationale of AED programmes is to reduce the time to first defibrillation.

Originally, defibrillation could only be performed by emergency care providers who were trained in ALS. Today it is often performed by lesser trained BLS personnel. AED eliminates the need for training in rhythm recognition and makes early defibrillation by untrained personnel practical and achievable.

The first automated implantable defibrillators were developed by Mirowski in 1970. In the past 40 yr, external defibrillation has become the most important tool for termination of lethal arrhythmias. The first successful defibrillation of ventricular fibrillation outside hospital was achieved by the Belfast Mobile Coronary Care Unit in 1966 and the first automated defibrillators appeared in Brighton in the late 1970s.[56 57]

SOME TECHNICAL NOTES ABOUT AED

Automated defibrillators are now available for use primarily outside hospital. The terms automated and shock-advisory defibrillators refer to external defibrillators that incorporate a rhythm analysis system. AED are attached to the patient by two adhesive pads with connecting cables to analyse the rhythm and deliver the shock. The information is given by voice or a visual display, or both, and the



Cardiac arrest
BLS algorithm if appropriate
Precordial thump if appropriate
Attach defib. monitor
Assess rhythm
± Check pulse
VF/VT
Non-VF/VT
Defibrillate × 3 as necessary
CPR 1 min
CPR up to 3 min
During CPR if not already:
· Check electrode/paddle position, contact
· Attempt/verify tracheal intubation and i.v. access
· Give adrenaline every 3 min
· Correct reversible causes
· Consider buffers antiarrhythmics atropine/pacing
Potentially reversible causes:
Hypoxia
Hypovolaemia
Hyper/hypokalaemia and metabolic disorders
Hypothermia
Tension pneumothorax
Tamponade
Toxic/therapeutic substances
Thromboembolic/mechanical obstruction

Figure 1 Adanced life support (ALS) algorithm for the management of cardiac arrest in adults. Note that each successive step is based on the assumption that the one before has been unsuccessful.[56]

actual delivery of the shock is triggered manually.

These systems have great potential for use by basic ambulance men who may not be trained in ECG interpretation. Although specificity for VF is approximately 100%, sensitivity for coarse VF is approximately 90–92%, for fine VF even lower and for VT only 50%.[23 32 87]

Moreover, in patients with an implanted automatic defibrillator, failure of the diagnostic algorithm has been documented when the patient also has an implanted pacemaker.[80]

The present equipment is relatively expensive, and performance is dependent on good maintenance.[4] A new generation of AED are now appearing on the market using new battery technology and some also have new waveform technology. They are small, simple, reliable and less expensive. Some of the new devices have the facility for ECG display. These new generation AED will stimulate widespread availability of defibrillators in ambulances, doctor's cars, places of work, public places, aeroplanes and cruise ships, etc.

EARLY DEFIBRILLATION BY FIRST-RESPONDING AMBULANCE PERSONNEL

Electrical defibrillation is the only effective therapy for VF. The chances of successful defibrillation decrease rapidly over time by more than 5% per minute. It has been demonstrated in Belgium and Sweden that bystander CPR can maintain the heart in VF longer, for approximately 10–15 min, and is therefore a bridge to first defibrillation.

In two-tiered EMS systems, the first ambulance generally arrives several minutes before the second ambulance, which usually has the defibrillator and medically qualified personnel on board. The Belgian CPCR registry showed that 69% of cardiac arrest

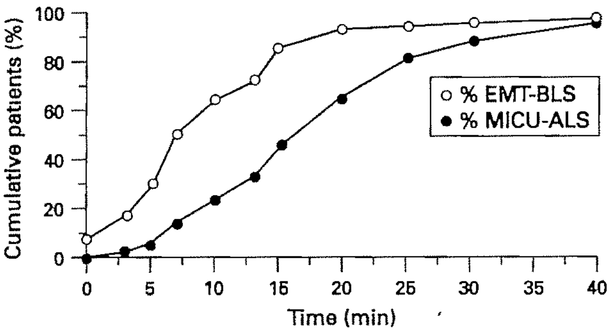


Figure 2 Cumulative inclusion of cardiac arrest patients by the first-tier ambulance (EMT-BLS) and by the second-tier ambulance (MICU-ALS), illustrating that the first-tier arrives significantly faster than the second tier.[19]

patients were first attended by the basic ambulance manned by two EMT; the median time interval between collapse and start of BLS resuscitation by the EMT was 8 min; the median time interval between collapse and defibrillation by the second-tier medical ALS team was 16 min. It was concluded that EMT can be expected to reach a substantial number of VF victims within a few minutes after collapse and many minutes before arrival of the medical ALS team (fig. 2).[19]

Therefore, it seemed logical to equip first-tiered ambulances with defibrillators and to train first-line ambulancemen in the use of AED. The expected result is that EMS systems, based on early defibrillation by first-line ambulancemen, will provide not only shorter times to initial countershock but also, by having delegated initial defibrillation to first responders, they will produce significantly shorter times to i.v. access, tracheal intubation and initial adrenergic drug therapy.[55]

AED training

Experiences in Scandinavia, the UK, Germany, Belgium and the USA have demonstrated that a training course of less than 8–10 h followed by 6-monthly refresher courses is sufficient to instruct an ambulanceman in the correct use of an AED according to a standard procedure. Knowledge of basic CPR is a prerequisite for successfully attending an AED course.

The AED training course and subsequent implementation of an AED programme, should be placed under full medical supervision. The course should include background information, knowledge of the equipment and its maintenance, and knowledge of the procedure, and should be tested by an examination. Formal 6-monthly refresher courses are needed, with feedback to discuss each intervention.

To achieve the goal of early defibrillation, ideally all emergency personnel responding to cardiac arrest should be trained, equipped and permitted to defibrillate.

Following the early pre-hospital experience in Belfast and Brighton, defibrillator technology has been developed further and systems are now implemented in many countries in a community wide basis. Early defibrillation with AED by ambulance personnel is now available widely in the UK and Scandinavia, and in parts of Germany and Belgium. Pilot studies are emerging in many European countries: France, Spain, Italy, Austria, Switzerland. In the Netherlands and Spain, all ambulances are manned by experienced nurses or doctors, or both, and are equipped with manual defibrillators.

As a result of these experiences it has been recognized that the success of an early defibrillation programme depends on the following factors:

- the programme should be placed under medical control
- the majority of arrests should be witnessed
- the time interval between cardiac arrest and first CPR should be <4 min
- the time interval between cardiac arrest and defibrillation should be <12 min
- there should be a minimum number of interventions
- there should be a programme of training and retraining
- there should be a programme for monitoring the performance of the programme.

SLOW IMPLEMENTATION OF AED BY FIRST-RESPONDING AMBULANCE PERSONNEL IN EUROPE

AED programmes are only partially implemented in continental Europe. Important reasons for this slow implementation include: lack of motivation and awareness; organization of EMS systems; and legal issues. Moreover, in the USA, widespread implementation of AED programmes has also been delayed by regulatory authorities.[31]

Awareness

In Europe, cardiovascular disease accounts for more than 45% of mortality. However, public awareness is most influenced by information provided by the media. In a recent survey in a sample of the adult Belgian population, only 8% of respondents answered that cardiovascular disease was their major concern, whereas the values were 18% for traffic accidents and 17% for AIDS.[9]

Organization

In all European countries access to the EMS system is by a specific telephone number. The European Union has recommended the use of 112 as the uniform European emergency telephone number.[14 24 42 106]

There is a wide variety of European EMS systems: one-tiered systems delivering BLS by an EMT (basic ambulance person); one-tiered systems delivering BLS and defibrillation by an EMT-d; one-tiered systems delivering BLS and ALS by paramedics, doctors and/or nurses; two-tiered systems delivering BLS followed by ALS; and two-tiered systems delivering BLS and defibrillation, followed by ALS (table 2). Best performance, in terms of survival, is obtained with systems with highly qualified staff provided they are available quickly.

The structure and organization of the EMS

Table 2 EMS systems in European countries. Local variations in the country are indicated between brackets. md=medical doctor, rn=nurse; pm=paramedic; EMT=emergency medical technician; EMT-d=emergency medical technician qualified for use of AED (*)In the presence of a doctor. systems in European countries, and the legal background for defibrillation practice are summarized in table 2

In the majority of continental European countries, doctors have an active role in pre-hospital emergency medical care, as part of the first or second tier. In most parts of Scandinavia and the UK, paramedics serve as members of the first or second tier. This medical presence on the field could be a reason for slow involvement of ambulance personnel in defibrillation.

Legislation

Because of historical, organizational, political and religious reasons, legislation relating to resuscitation and defibrillation is different in European countries. In countries where historically only ambulancemen and paramedics were present in the field, implementation of early defibrillation by ambulancemen was easy. However, in countries where a medical presence was prominent in the second or even in the first tier, introduction of defibrillation by first-line ambulancemen was much slower.

Information on legal regulations has been collected from 28 European countries:

Providing help. In all European countries (except the UK, where there is no legislation), anyone is legally obliged to provide help to endangered persons.

Providing CPR. In 20 of 28 countries, anyone (or anyone who has been instructed) is legally allowed (or not forbidden) to start CPR. In five countries there is no specific legislation and in three countries CPR is restricted to health care professionals. In seven of 28 countries anyone who has been instructed, in 12 of 28 any health care professional (whether or not in an official capacity), and in four of 28 countries only doctors are legally obliged to start CPR. In five countries there is no specific legislation.

Providing defibrillation. In most European countries, defibrillation was considered until recently to be solely a medical intervention, which reflects the historical involvement of doctors in out-of-hospital emergencies and major incidents. In four of 28 countries the law restricts the act of defibrillation exclusively to doctors, and in five countries only nurses can be delegated to defibrillate. In six countries, ambulance personnel are allowed to defibrillate only in the presence of a doctor. In 11 of 28 countries defibrillation can legally be performed by nurses, paramedics or qualified health care professionals. In the UK and Spain there is no legal restriction on providing defibrillation. This means that in at least 10 European countries the law is an obstacle for nationwide implementation of AED programmes by non-physicians. In countries where nurses may be allowed to defibrillate, there is a potential problem for ambulances that are manned by EMT.

The cost of hardware is decreasing for new generation devices. Training and re-training are very demanding and require substantial effort and logistic solutions. Other major obstacles are public and political awareness, tradition and structure of the EMS systems, and motivation of the medical community. Increasing public and political awareness and increasing motivation in the medical profession can help to overcome these obstacles.

RESULTS OF AED PROGRAMMES OF EARLY DEFIBRILLATION BY FIRST-LINE AMBULANCE PERSONNEL

Reported data on survival after cardiac arrest caused by VF by non-medically qualified personnel using an AED, range from 4 to 31%.[6,26,43,48,63,78,79,92,99] These variations may be related to: differences in characteristics of the treated population; differences in methodology and quality of registration; and differences in the performance of the AED programme.

One of the key elements that determines success of an AED programme is the percentage of cardiac arrest patients found in VF, which is a reflection of the speed of intervention of the EMS system. Reported incidences of VF in different cities and countries around the world range from 62% to less than 10%. As expected, there is a significant correlation between the incidence of VF and subsequent survival. As a consequence, it is unclear if the reported differences in survival rates are a result of differences in system organization, treatment procedures or in the skills of the personnel.

The "Utstein style" presents a glossary of terms and reporting guidelines for description of cardiac arrest, resuscitation, the EMS system and outcome, and was published by representatives of the American Heart Association, the European Resuscitation Council, the Heart and Stroke Foundation of Canada, the Southern African Resuscitation Council and the Australian Resuscitation Council. The recommendations were published simultaneously in *Circulation*, *Resuscitation*, *Annals of Emergency Medicine* and other major journals. The in-hospital "Utstein style" has been published in 1997.[18,27,28]

IMMEDIATE DEFIBRILLATION BY FIRST-LINE TRAINED INDIVIDUALS

As considerable time may elapse between the onset of VF and arrival of the emergency medical services, immediate defibrillation by first-line trained bystanders may be the long-term realization of the concept of early defibrillation. A first responder is defined as a trained individual, acting independently within a medically controlled system.

Although immediate first-responder defibrillation is the logical theoretical next step after implementation of defibrillation by ambulance personnel, there is at present no evidence that bystander defibrillation increase survival rates. There have been occasional cases of defibrillation in-flight and in a railway station.

Programmes should be developed to test the principle that first responders assigned to the management of cardiac arrest in the community should be trained and permitted to defibrillate. This could include police, security officers, life guards, voluntary aiders and those assigned to provide first aid at their place of work. Every programme designed to implement first-line defibrillation should be evaluated critically to assess if first-line defibrillation increases survival.[40,62,76,84,104,105]

Conclusions

Cardiorespiratory arrest caused by sudden arrhythmia as a consequence of myocardial ischaemia or infarction continues to be a leading cause of unexpected death in the community. Increased public education in the recognition of early symptoms and signs of a heart attack is likely to achieve a significant reduction in the present mortality and morbidity of out-of-hospital heart attack.

Electrical defibrillation is the single most important therapy for the treatment of VF. The time interval between onset of VF and delivery of the first defibrillation shock is the main determinant of survival. This should be as short as possible. Early defibrillation has a crucial role in the chain of survival. To achieve the goal of early defibrillation, it is mandatory to allow individuals other than doctors to defibrillate. At present, however, early defibrillation by ambulance personnel using automated external defibrillation (AED) is not yet widely implemented.

Obstacles to implementation of AED by ambulance personnel are: legislation, structure of EMS system, economic priorities, awareness, motivation and tradition. It is also recognized that success of an early defibrillation programme is dependent on the following factors: the programme is placed under medical control; the majority of arrests are witnessed; the time interval between cardiac arrest and first CPR is usually <4 min; the time interval between cardiac arrest and defibrillation is usually <12 min; there is a minimum number of interventions; there is a programme of training and re-training; and there is a programme for monitoring the performance of the programme.

Recommendations

- The medical profession is urged to increase awareness of the public and of those responsible for emergency medical services and regulatory powers to permit changes in practice and legislation where necessary.
- It is essential to integrate the concept of early defibrillation into an effective emergency cardiac care system. This is best characterized by the "chain of survival" concept, which includes early access to the emergency medical services (EMS) system, early cardiopulmonary resuscitation when needed, early defibrillation when indicated and early advanced cardiac care.
- All *emergency personnel* should be trained and permitted to operate an appropriately maintained defibrillator if their professional activities require that they respond to persons experiencing cardiac arrest. This includes all first-line emergency personnel working in an organized EMS system, both inside and outside hospital (e.g. emergency medical technicians (EMT), non-EMT first responders, fire fighters, volunteer emergency personnel, physicians, nurses and paramedics).
- All emergency ambulances and other emergency vehicles that respond to or transport cardiac patients should be equipped with a defibrillator.
- Defibrillation should be a core competence of professional nurses, and defibrillators should be available widely on general hospital wards.
- All defibrillator programmes must operate within medical controls by qualified and experienced physicians. They should ensure that every link of the chain of survival is in place and should have access to all information required to permit system audit.
- To monitor the programme, there must be appropriate registration of the interventions according to the Utstein style.

Immersion, near-drowning and drowning

F. ST C. GOLDEN, M. J. TIPTON AND R. C. SCOTT

"Drowning" is defined as "suffocation by submersion, especially in water"[66]; it continues to be the third most common cause of accidental death in the general population and, for children in many countries, the second most common cause after road accidents.[75] In the USA, 40% of drowning victims are less than 4 yr old.[74] In Britain, the Office of Population Census reports that child deaths from this cause continue to be the third most common cause of accidental death after road accidents and burns.

"Near-drowning" is defined as "survival, at least temporarily, after suffocation by submersion in water".[65] We would challenge this definition as most dictionaries define "suffocation" as cessation of breathing leading to *unconsciousness* or death. However, pulmonary complications may follow aspiration of water without cessation of breathing or loss of consciousness. Thus "near-drowning" should be defined as "survival, at least temporarily, after aspiration of fluid into the lungs". The importance of the distinction between the two definitions is that aspiration of fluid may lead to later pulmonary complications, even in those *without* a history of loss of consciousness, and thus care must be exercised in the management of *all* patients with a history of aspiration. Modell, Graves and Ketover reported[68] that in dogs, aspiration of as little as 2.2 ml/kg body weight produced a decrease in Pa_{O_2} to approximately 8 kPa (60 mm Hg) within 3 min. Pulmonary surfactant is altered locally by water in the alveoli resulting in pulmonary shunting via either fluid-filled (salt water) or atelectatic (fresh water) alveoli. Pearn[78] stated that within minutes after inhalation of as little as 2.5 ml/kg body weight, the normal intrapulmonary shunt of approximately 10% may increase to as much as 75%. Even victims who are conscious, alert and outwardly clinically normal after a near-drowning incident may take several days to revert to pre-immersion values.[78] After aspiration of either fresh or salt water there may be delayed outpouring of fluid into the alveoli, secondary to pulmonary parenchymal damage with transudation of protein rich fluid, so called *"secondary drowning"*,[77,82] with consequent impairment of gas exchange. Orlowski[74] cited several cases who appeared normal on assessment in the emergency department, even with normal chest x-rays, but who developed fulminant pulmonary oedema as long as 12 h after the near-drowning incident.

While statistics on the incidence of drowning deaths are available for most nations, there are no precise data for near-drowning incidents, although in the USA they are estimated to be 500–600 times more common than their fatal counterpart.[75] In Britain, a comprehensive hospital survey for the years 1988–1989 by Kemp and Sibert[53] of 330 drowning and near-drowning incidents in children reported 142 deaths and 188 survivors.

One of the great tragedies of drowning or near-drowning is that the victims, frequently young, are generally in good health before the unexpected event which resulted in death or brain damage in a number of survivors. In recent years increased public awareness of the general principles of basic life support and cardiopulmonary resuscitation (CPR) has resulted in many more near-drowning victims arriving in hospital in a state capable of being resuscitated. The many contemporary reports in the literature of apparently hopeless cases being successfully resuscitated, particularly after cold water submersion,[11,20–22,38,45,53,54,59,85,86,102] has led to protracted resuscitative efforts by hospital personnel.

Drowning and near-drowning have been the subject of many reviews.[15,64,66,74,78,88] While resuscitation and the subsequent respiratory management of the near-drowning patient is now well established and largely non-controversial, the remaining major therapeutic challenge is limitation of brain damage in survivors with its associated consequent human and economic costs. Although the success stories tend to be reported, in the absence of full statistical information it is difficult to obtain an overall picture of the ratio of those who have been resuscitated and left with or without residual brain damage.

The criteria used to identify those with a poor prognosis needs to be refined. Some centres, based on retrospective analysis, have reported their results of various treatment regimens with suggested predictive criteria for recovery without severe brain damage.[34,53,68,74] Regrettably, these criteria are often

(*Br. J. Anaesth.* 1997; **79**: 214–225).

Key words
Drowning. Hypothermia. Heart, cardiopulmonary bypass. Heart, resuscitation. Immersion.

F. ST C. GOLDEN, MB, BCH, PHD, M. J. TIPTON, MSC, PHD, Robens Institute, University of Surrey, Guildford, Surrey GU2 5XH. SURGEON COMMANDER R. C. SCOTT, MB, BSC, BCH, FRCA, Royal Navy, RH Haslar, Gosport, Hants PO12 2AA.

conflicting and thus of little real value other than to act as a reminder that long-term complications occur and caution should be exercised in discussing prognosis with relatives in the early stages. One of the problems appears to be that, although the protective role of hypothermia is now generally recognized, it is not always possible to determine from deep body temperature on arrival at hospital what the cerebral temperature was before severe hypoxia developed.

This review examines the physiological considerations of accidental immersion and discusses the factors which may influence outcome. The recommended management of such victims is also reviewed, with particular emphasis on the role of cardiopulmonary bypass.

Physiological considerations

IMMERSION IN THERMONEUTRAL WATER

The physiological effects of immersion in thermoneutral water have been reviewed previously by Epstein.[24] In sum, changes which occur are largely a consequence of the effects of the external hydrostatic pressure on the resilient body tissues and gas-containing body cavities during head-out immersion. This results in physiological alterations in the cardiovascular and respiratory systems, and in the gastrointestinal tract. The increase in venous return causes a 32–66% increase in cardiac output, increase in right to left shunting as a result of a combination of pulmonary pooling, cephalic movement of the diaphragm and, to a lesser extent, minor compression of the chest wall; overall there is a 65% increase in the work of breathing. The central shift in blood volume is sensed by the body as hypervolaemia and results in diuresis, natriuresis and kaliuresis.[25]

From a practical viewpoint there is little evidence that these changes cause respiratory or circulatory embarrassment in a healthy individual.[61] However, during rescue, after protracted immersion in warm water, or relative shorter immersion in cold water when hypothermia may be present, circulatory collapse and cardiac arrest may occur. This phenomenon, which has been termed "circum-rescue collapse" is considered to be outside the scope of this article and has been reviewed elsewhere.[32]

IMMERSION IN COLD WATER

The increase in right atrial pressure, resulting from reflex peripheral cold vasoconstriction after immersion in cold water, is additive to the hydrostatic pressure effect described above and enhances urinary output by as much as one-third.[55] However, of more importance to the accidental immersion victim are a group of cardiorespiratory reflex responses which can occur on sudden immersion in cold water and last for approximately 2–3 min. These responses, collectively known as the "cold-shock" response, have been reviewed by Tipton.[91] They are initiated by a rapid decrease in skin temperature and are probably responsible for the majority of near-drowning incidents and drowning deaths after accidental immersion in open waters in the UK. Respiratory drive is enhanced on immersion in water colder than 25 °C[52] and is inversely related to water temperature, reaching a maximum level with immersion in water at 10 °C.[96] The response includes an initial "gasp" of 2–3 litre in an adult, followed by uncontrollable hyperventilation which can result in a 10-fold increase in minute ventilation[93] which significantly reduces Pa_{CO_2}.[51] The inspiratory shift in end-expiratory lung volume after cold water immersion can result in tidal breathing within 1 litre of total lung capacity, creating a sensation of dyspnoea. This, coupled with the swim stroke/respiration asynchrony caused by hyperventilation, makes swimming very difficult, and is believed to be one of the major causative factors in the mechanism of cold-water swim failure.[31]

The maximum breath-hold times of normally clothed individuals are reduced to less than 10 s.[92] As a consequence, on immersion in choppy or turbulent water where the airway may be intermittently submerged, there is a significant chance of aspiration during the first few minutes. Breath-holding to facilitate escape from a submerged vehicle may be equally difficult and result in entrapment and drowning, or possibly near-drowning in those who manage to escape or are rescued before a lethal volume of water is aspirated, approximately 22 ml kg^{-1}.[68]

The initial cardiovascular responses to cold immersion include an immediate intense reflex peripheral vasoconstriction, 42–49% increase in heart rate and 59–100% increase in cardiac output,[40] with a resulting increase in arterial and venous pressures. These responses significantly increase the workload of the myocardium and, coupled with the concomitant increased catecholamine response,[5 16 48] may induce undesirable cardiac arrhythmias.

Thus in healthy young people, who may be competent swimmers but unhabituated to cold, the initial respiratory responses to immersion in cold water may cause short-term incapacitation which could prevent them from relaxing and swimming a short distance to save their lives. In turbulent water, or if escape from a submerged vehicle is necessary, the inability to breath-hold for more than 10–20 s may result in aspiration and near-drowning, or even drowning.

Additionally, in middle-aged or elderly people with heart disease, hypertension or vascular disease, the initial cardiovascular responses to immersion in cold water may precipitate a cardiovascular accident. It is considered that this mechanism as a cause of incapacitation resulting in drowning is probably underestimated. The eyewitness reports of the sudden cessation of movement in some drowning victims[66] is more suggestive of sudden circulatory malfunction. The fact that aspiration may occur subsequent to a cardiovascular incident may mislead some into concluding that drowning was the only problem requiring treatment or the cause of death.

Given the above, it is perhaps less surprising to discover that 60% of the annual open water immersion deaths in the UK occur within 3 m of a safe refuge, and two-thirds of those who die were regarded as "good swimmers".[44]

HYPOTHERMIA

"*Hypothermia*", defined as a deep body temperature <35 °C,[81] is an inevitable consequence of protracted immersion in cold water and appears to play an important role in the successful outcome of those who have survived prolonged submersion. The mechanism of how deep body temperature is reduced so rapidly in some of these victims is less clear.

The rate of change of core temperature in an immersed body is dependent on the inter-relationship of several physical and physiological factors such as water temperature, relative movement of water adjacent to the skin, body surface area to mass ratio, insulation, peripheral circulation, metabolism or conditions which may affect any of these factors (e.g. injury, intoxication, etc).

With continued body cooling, consciousness becomes progressively impaired until it is lost at a deep body temperature of approximately 30 °C.[17] Cerebral blood flow decreases in proportion to the reduction in metabolism,[42] while Stone, Donnelly and Frosbese[89] reported a 6–7% reduction for each decrease in core temperature of 1 °C; cerebral activity is abolished at brain temperatures less than 22 °C.[1] However, these data relate to anaesthetized patients in whom shivering was controlled. In victims of accidental immersion in cold water whose airway is being maintained clear of the water by a life jacket, shivering is pronounced with a resulting increased production of carbon dioxide, at least in the early stages, until body temperature decreases to approximately 29 °C. Should ventilation be impaired however, shivering is depressed or even absent while hypercapnia produces cerebral vasodilatation which increases cerebral perfusion.

With further cooling, in spontaneous breathing adults, cardiac arrest from ventricular fibrillation (VF) may occur at a deep body temperature <28 °C, or asystole at approximately 24–26 °C.[3] However, with surface cooling, when core temperatures decrease to 35–33 °C, skeletal muscle temperatures are usually at or below 28 °C when neuromuscular performance is significantly impaired, making swimming or other actions necessary for survival extremely difficult.[94] Therefore, it is likely that most immersion victims, excepting those wearing a life jacket with a "spray hood",[28] aspirate water as consciousness becomes impaired (i.e. as core temperature decreases to less than 34 °C) and thus well before significant protection from cerebral hypoxia is bestowed.

In spite of the ability of cold water to extract heat from the immersed body, hypothermia *per se* is unlikely to be a problem within 30 min of head-out immersion for a healthy, clothed adult, even in water as cold as 5 °C. The normal physiological responses to cold reduce heat transfer by mass flow (circulation) to the surface from the deeper tissues and increase shivering heat production by as much as five-fold.[30] As a general rule, however, in spite of these responses, during head-out immersion in laboratory conditions, deep body temperature of the average adult wearing outdoor clothing has fallen to 35 °C after approximately 1 h in water at 5 °C, 2 h in water at 10 °C, and 3–6 h in water at 15 °C.[94] In open water however, because of the rich supply of blood vessels to the scalp which do not vasoconstrict in the cold, heat loss from the unprotected head may be enhanced by forced convection and evaporation thereby increasing the rate of body cooling considerably. Similarly, if the head is immersed the rate of body cooling is significantly faster.

Because of their greater surface area to mass ratio and reduced subcutaneous fat content, cooling rates of immersed children are also significantly faster than those seen in adults. However, with surface cooling alone, even in children, rates for decrease in body temperature are too slow to cool the brain sufficiently to protect it from the hypoxia encountered in drowning asphyxia. In anaesthetized naked infants, being surface cooled for surgery with ice packs and ice cold water, rectal temperatures decreased by as little as 2.5 °C in the first 10 min of the procedure, and it took 32.5 min for it to reduce to 24–25 °C.[70] Thus if cerebral hypothermia is the mechanism through which some children can survive protracted submersion without sustaining lasting hypoxic neurological damage, an alternative method of heat exchange to surface cooling alone must be found.

To date it has been postulated by several authors[23 29 33 35 59 71 78 86] that the "mammalian diving response", either alone or in combination with hypothermia,[33] may be the explanation.

DIVING RESPONSE

The diving response, characterized by apnoea, generalized marked peripheral vasoconstriction and bradycardia[18 23] is initiated reflexly by stimulation of the ophthalmic division of the trigeminal nerve on immersion of the face in cold water. It plays a powerful role in oxygen conservation in diving animals, enabling some to remain submerged for periods in excess of 30 min. The response is enhanced by both anxiety and cold water. The magnitude of the diving response found in humans is qualitatively similar to that found in diving mammals, but quantitatively less marked, with the cold-shock response predominating in the majority of normally clothed adults.[92] Nevertheless about 15% of people do show a profound reaction[23] and this percentage increases with the use of specialist protective clothing, such as immersion "dry" suits,[92] which prevent rapid cooling of the cutaneous thermal receptors of the majority of the body, but leave those of the face exposed to the cold stimulus. Tipton, Kelleher and Golden[95] have reported that in such circumstances, where the cold-shock and diving responses are stimulated in roughly equal proportions, the resulting fluctuation in the competing parasympathetic and sympathetic chronotropic influences to the heart frequently (in 31 of 36 immersions) caused a variety of cardiac arrhythmias (predominantly supraventricular) just after the cessation of breath-holding in cold water.

The diving response is also reported to be more marked in infants than adults.[18] Gooden, in his excellent review,[33] argued that while the diving response alone is unlikely to explain the reported survival of those cases of protracted submersion in cold water, it does play a contributory role together with hypothermia. He hypothesized that survival from prolonged near-drowning appears to depend on a specific interplay between the diving response and hypothermia, resulting in a protective state of "hypometabolism". Peripheral vasoconstriction, associated with both the diving response and cold, depresses tissue metabolism and thus reduces body oxygen requirements. Gooden postulated that immediately on face immersion the diving response apnoea prevents water aspiration into the lungs. Even if water does enter the larynx he postulated that reflex glottal spasm prevents further penetration into the lungs. The associated bradycardia and selective redistribution of blood conserves oxygen stores thereby protecting the brain from hypoxia during the initial minutes of immersion. Gradually, with surface cooling, hypothermia develops so that by the time oxygen stores are depleted, cerebral metabolism has been reduced to a level which confers some protection from hypoxia.

While to some extent this hypothesis is plausible there are several questions that remain to be answered. First, why is it that in most cases of prolonged submersion who survived, sufficient water was aspirated to cause near-drowning? It is possible that aspiration, when it did occur, was a relatively terminal event when the diving response, or laryngospasm, could no longer be maintained because of profound hypoxia. However, from our understanding of surface cooling, discussed above, it is probable that profound hypoxia is present before significant brain cooling has occurred in this circumstance. Second, does the cold-shock response override the diving response in children as it does in adults?[41 92] The only evidence in the literature relating to children in this context is that of Ramey, Ramey and Hayward[80] who found that children could not hold their breath long enough for a diving response to occur; in their experiment however, the temperature of the water was 29 °C, above that normally associated with the initiation of the most powerful diving response. Skin temperature of children already playing in water is at or in the region of the water temperature and thus, if they become accidentally submerged, should not exhibit a cold-shock response. However, those children who fall into water without prior wetting should display a cold-shock response. Finally, another factor mitigating against the "hypometabolism" hypothesis is the large discrepancy in the rates of cooling reported (varying from 10 °C in 10 min in ice water[75 102] to 3.5 °C in 6 min in a young adult[85]). Such rates of cooling are not compatible with either surface cooling alone or in combination with a diving response.

Thus while not ruling out entirely the participation of the diving response in the early stages of some of these remarkable survival stories, it is considered that the rapid rates of cerebral cooling encountered may be largely dependent on pulmonary heat exchange after aspiration.

PULMONARY AND GASTRIC COOLING

After submersion, the victim may attempt to breath-hold for as long as possible before neurogenic afferents from the respiratory muscles or cutaneous thermoreceptors build to an intolerable level, forcing the individual to take a breath.[101] It has been shown that voluntary breath-holding can be extended by movements of the respiratory muscles, and swallowing, against a closed glottis.[101] This may be the explanation for the large amounts of water reported to have been found in the stomach of some drowning victims[11 27 67 78] but not in others[33] (i.e. ingestion of water is only likely to be found in those who attempted to extend voluntary breath-holding). Depending on the volume and temperature of the water swallowed, heat exchange between the blood and gastric wall could contribute significantly to blood cooling, especially in children. When continued breath-holding is impossible, aspiration of water into the airways and alveoli occurs with inspiration and possibly reflex coughing, provided reflex laryngeal spasm does not supervene.

Regardless of the method of entry of cold water into the "core" of the body, be it lungs, stomach, or both, it precipitates a decrease in deep body temperature. The magnitude of this decrease is directly proportional to the volume of water aspirated, its temperature differential with the body and state of the circulation. However, to protect the brain from hypoxic damage it would be necessary to cool the brain very rapidly, at least 7 °C in 10 min. This doubles cerebral hypoxia survival time[46] but even colder brain temperatures are required for longer survival periods.

Gooden[33] argues that, to explain some of the remarkable survival stories reported, such a mechanism of cooling lacks quantitative evidence. On simple thermal physical principles of "methods of mixtures", he points out that "a (normal) person would need to ingest an amount of ice-cold water equivalent to 20% of body mass in order to reduce the average body temperature to 30 °C. Thus a child weighing 20 kg would need to ingest approximately 4 litre of ice-cold water". Such volumes of aspirated water are not compatible with resuscitation[68] nor are they usually encountered in near-drowning victims.[36] Harries[37] stated that it is unusual to aspirate more than 200 ml but it is unclear how this estimation has been determined, particularly as it has been shown experimentally[69] that aspirated fresh water is quickly absorbed and redistributed within the body.

Gooden's calculation, however, appears to be based on the requirement for the entire body mass to be cooled to 30 °C. Using the same simple methods of mixtures, the volume of ice water necessary to cool the blood volume of a 20-kg child (approximately 1.6 litre) to 30 °C would be approximately 300 ml. It is accepted that this is a gross over simplification as the actual amount required to be aspirated to cool the brain would need to be in excess of this because of the dynamic heat exchange that would occur with the perivascular tissues and perfused organs; in addition, pulmonary heat exchange is reduced because of pulmonary shunting. Nevertheless, given that a large proportion of the cardiac output in a child in such circumstances (i.e. with generalized peripheral vasoconstriction) is diverted to the cerebral circulation, it is conceivable that selective cooling of the brain occurs some time before the general body mass equilibrates. Thus aspiration of cold water may play a critical role in the production of cerebral hypothermia and brain survival in the submerged child or young adult of relatively small body mass.

At first sight the volume of water required to be aspirated would appear to be in conflict with Modell's conclusion that volumes in excess of 22 ml kg^{-1} are usually incompatible with life. This would allow a maximum aspiration of 440 ml for a child with a body mass of 20 kg. While this is more than the theoretical 300 ml to cool the blood, as stated above, larger volumes would in reality be required to negate dynamic heat exchange with the perivascular tissues and perfused organs. However, during the drowning process, aspiration of water is unlikely to occur in one single bolus but is more likely to be a dynamic process with flushing of small volumes of cold water in and out of the lung. Fainer, Martin and Ivy[26] demonstrated in dogs that rapid violent respiratory movement continued for about 70 s after submersion. It is proposed that with each tidal volume of water aspirated, heat is exchanged but the total volume retained in the lungs when respiration ceases is significantly less than the total volume of water which has entered and exited the lungs up to that time.

This hypothesis is supported by a recent animal experiment by Conn and colleagues[16] which showed that aspiration of cold water produces extremely rapid blood cooling; in lightly anaesthetized dogs, the mean carotid artery temperature decreased by approximately 8.0 °C in the first 2 min of drowning, but only by 0.8 °C in a control head-out group of similarly shaved dogs; rectal temperature lagged "considerably behind". Regrettably the experimental method did not make it possible to estimate how much fluid had been aspirated in those 2 min. When the animals were killed after 10 min of submersion, the volumes aspirated, estimated from post-mortem weight changes, were considerably in excess of the accepted lethal level of 22 ml kg^{-1}.[68] Incidentally, it is quite difficult to find the origin of the value of 22 ml kg^{-1} quoted frequently by Modell and others; in the original report by Modell and Moya,[69] the value appears to be 20 ml lb^{-1}, with death caused by VF rather than irreversible pulmonary damage.

The theory of water flushing in and out of the lung rather than absorption of water as the primary cause of the rapid cooling of blood on submersion is supported further by data from Conn and colleagues.[16] The marked decrease in carotid artery blood temperature in dogs (average weight 9.2 kg) was 8.5 °C after 2 min in fresh water at 4 °C and 7.5 °C in salt water; while over the remaining 8 min of the experiment, mean carotid temperature decreased by another 2.4–10.9 °C in fresh water and by 3.1–10.6 °C in salt water. Body mass increased by 1.5 kg (fresh) and 0.6 kg (salt) in the 10 min. Although Conn and colleagues[16] reported that all animals were tachypnoeic on immersion, the study did not state when respiration ceased. In an earlier experiment by Fainer, Martin and Ivy,[26] using 160 dogs, it was reported that violent respiratory movement lasted approximately 71 s and thereafter respiratory movement was limited to the occasional agonal movement. Thus it would be fair to assume that, in the experiment by Conn and colleagues,[16] most of the aspiration had taken place during the 2-min period showing the greatest decrease in carotid temperature. Furthermore, if one assumes no, or little, absorption in the salt water group in this time, it suggests that in the equivalent fresh water group, 7.5 °C of the 8.5 °C decrease in blood temperature in the initial 2 min was caused by flushing and 1.0 °C by absorption of approximately 900 ml of fresh water.

AMBIENT COOLING

Increasingly, hypothermia has been recognized as a favourable prognostic indicator. However, the rate of onset of hypothermia is clearly critical; to be of benefit it must occur rapidly before profound hypoxia develops.

Exposure to cold ambient conditions during resuscitative procedures, while awaiting the arrival of the ambulance, facilitates continued cooling if adequate insulation is not provided. Furthermore, thermoregulation in the hypoxic individual is likely to be severely compromised. This, combined with high evaporate heat loss from wet clothing and increased conductive heat loss to the ground beneath the supine patient, cause deep body temperature to continue to decrease. By the time the victim arrives at hospital, body temperature, in a patient with intact circulation, may have decreased significantly. Unless such a decrease occurs quickly, and before hypoxia becomes severe, little useful cerebral protection is provided.

Thus cooling which occurs during rescue and transport to hospital is of little benefit and may render deep body temperature on arrival in hospital an unreliable prognostic indicator.

Rescue and treatment

RESCUE

Advice on rescue lies more correctly with rescue organizations but a few important principles are offered for consideration:

At all times it is important to ensure the safety of the rescuer in addition to the casualty.

- Landing a casualty should never be delayed to enable attempts at in-water resuscitation.
- Where possible, casualties wearing life jackets whose airway is clear of the water should be recovered in a horizontal attitude.[32]

- The possibility of cervical spine trauma should be considered in unconscious victims rescued from shallow water and appropriate measures and techniques used.[37]

TREATMENT

Out-of-hospital management

It should be presumed that all near-drowning victims rescued from UK open waters are hypoxic, acidotic and hypothermic.

The primary aims of treatment of the near-drowned are listed below in order of priority:

- Effective immediate relief of hypoxia. The speed of achieving this has the greatest influence on outcome.[73,87]
- Restoration of cardiovascular stability.[87]
- Prevention of further heat loss.
- Speedy evacuation to hospital.

Airway patency and adequate ventilation should be achieved rapidly. There is a significant risk of regurgitation and aspiration of gastric contents during resuscitation.[74] Tracheal intubation, if indicated, should be carried out at the earliest opportunity.[87] High fractional inspired oxygen ($F\mathrm{IO}_2$) should be delivered using a self-inflating bag and reservoir; if available, a positive end-expiratory pressure (PEEP) valve set to 5 cm H_2O should also be used. Application of cricoid pressure during EAR, or bag and mask ventilation, reduce the risk of regurgitation and aspiration.[74]

The use of the Heimlich manoeuvre in near-drowning has been considered by the Emergency Cardiac Care Committee of the American Heart Association and is not recommended.[83] There is insufficient evidence to support the claims that it is effective in removing aspirated liquid. Additionally, the manoeuvre itself may delay early intubation, aggravate visceral or spinal injury, cause confusion among rescuers with yet another procedure to follow,[83] induce vomiting[74] and increase the risk of precipitating an undesirable cardiac arrhythmia in the hypothermic casualty rescued from cold water.

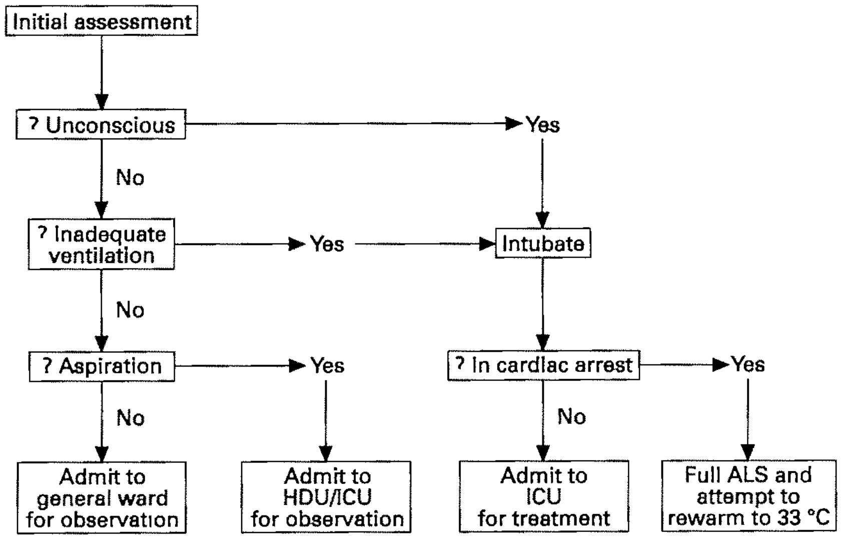
In the hypothermic near-drowning casualty, because of the marked cold-induced peripheral vasoconstriction, characteristically low volume and profound bradycardia, peripheral pulses are notoriously difficult to feel. Accordingly, the carotid artery should be palpated gently for at least 1 min.[37,74] Extreme caution must be taken not to precipitate VF by rough handling.[75] VF responds poorly to defibrillation at core temperatures less than 28 °C; at this temperature, Purkinje tissue looses its conduction advantage over normal ventricular muscle fibres. Nevertheless, it may be worth attempting, especially in children, as some successes have been reported.[88,100] However, even when sinus rhythm is achieved at these temperatures it tends to be unstable and revert easily to VF. If attempts at defibrillation at less than 28 °C are not immediately successful they should be discontinued until cardiac temperature increases to greater than 29 °C.

The casualty should be insulated against further heat loss and transported to the nearest emergency department as rapidly as gentle handling allows.[88] Any life-support measures instituted at the scene should be continued during transportation.[74] Some authors advocate immediate transfer of all severely hypothermic and clinically lifeless patients to the nearest facility with cardiopulmonary bypass facilities.[11,60]

Hospital management

Near-drowning is an emergency: even those victims who appear normal on arrival at hospital can deteriorate rapidly.[74] An accurate, rapid initial assessment of the victim is essential. A suggested algorithm for subsequent management, based on the classification by Simcock of near-drowning victims,[87] is shown in figure 1.

Survival figures for victims of near-drowning are very encouraging for those with a minimal reduction in the Glasgow coma score (GCS) but much less favourable for those with low scores.[34,74] Factors



Initial assessment

No
Admit to general ward for observation
Admit to HDU/ICU for observation
Admit to ICU for treatment
Full ALS and attempt to rewarm to 33 °C

Figure 1 A suggested algorithm for management of near-drowning, based on the classification by Simcock of near-drowning victims.[87] ALS=Advanced life support.

Table 1 Favourable prognostic indictors for near-drowning

- Children 3 yr+[9 73]
- Female[34]
- Water temperature <10 °C[11]
- Duration of submersion <5 min[73], <10 min[9]
- No aspiration[9]
- Time to effective basic life support <10 min[73]
- Rapid return of spontaneous cardiac output
- Spontaneous cardiac output on arrival in emergency department[10 69]
- Core temperature <35 °C[9], <33 °C[10]
- Minimum blood pH >7.1[73]
- Blood glucose <11.2 mmol litre^{-1}[6 34]
- GCS. no coma on admission[34 69 73]. GCS >6[19]
- Pupillary responses: present[34 69]

which have been associated with favourable outcome are listed in table 1, but none, either individually or in combination, has been shown to have absolute predictive significance.[9] Therefore, full resuscitative efforts should be attempted in all near-drowning patients arriving in emergency departments.

Patients with no evidence of aspiration

Victims of near-drowning who appear normal in the emergency department can deteriorate unexpectedly. All should be admitted to a general ward for a period of observation, generally accepted to be a minimum of 6 h.[37] Other authors, however, consider it prudent to admit the victim for 24 h because of the risk of late onset pulmonary and cerebral oedema.[68 75 87] It is recommended that the investigations listed in table 2 are considered. Hypothermic patients who are conscious and cooperative can be rewarmed in a bath of warm water (40 °C) until rectal temperature has increased to 36 °C. Arterial blood-gas values, obtained while breathing air, and core temperature must be normal before discharge. Signs of aspiration, which may become manifest later, include cough, tachypnoea, retrosternal discomfort, audible crackles on auscultation of the chest, abnormal arterial oxygen tension with the patient breathing air, abnormal chest x-ray and fever.

Infection after immersion is common; usually this is confined to the chest, although there are reports of intracerebral abscess and septicaemia.[37] However, the benefits of prophylactic antibiotic therapy have been questioned.[74] It is generally agreed that antibiotic therapy should be withheld until bacteriological studies, or clinical examination, indicate active infection.[68] Patients should be informed of the potential seriousness of any pyrexial illness which develops within a few days of discharge. They should be advised to attend either their general practitioner or return to the A&E department in such an event.

Table 2 Suggested investigations for near-drowning patients

- Arterial blood gas analysis
- Biochemistry:
  - Electrolytes
  - Glucose
  - Urea and creatinine
  - Total creatinine kinase
- Coagulation studies
- Haematology
- Blood and tracheal aspirate for aerobic and anaerobic culture
- Chest radiograph
- Electrocardiogram
- Rectal temperature measured at least 15 cm from the anal sphincter
- Drugs screen for overdose of:
  - Alcohol
  - Tricyclics
  - Benzodiazepines
  - Paracetamol
  - Aspirin, etc

Patients with evidence of aspiration but without ventilatory compromise

These patients may develop pulmonary oedema and deteriorate precipitously. Accordingly, they should be admitted to a high dependency (HDU) or intensive care unit (ICU). Monitoring should include continuous pulse oximetry and frequent arterial blood-gas analysis. The onset of pulmonary oedema is usually within a few hours of aspiration of water, either fresh or salt, and can be rapidly progressive. Continuous positive airways pressure (CPAP) support provided by a mask or nasal cannula (in infants who are obligate nasal breathers),[74] should be offered in the first instance. The aim is to achieve an arterial oxygen partial pressure (Pa_{O_2}) of more than 8 kPa with an FI_{O_2} less than 0.5. If this is unsuccessful the facility for tracheal intubation and intermittent positive pressure ventilation (IPPV) with PEEP must be available immediately.

Patients with ventilatory compromise or hypothermia, or both

Patients who have clinical or investigative evidence of inadequate ventilation must undergo tracheal intubation and ventilatory support with PEEP.[68] This should be maintained at 8–10 kPa or at 10–12 kPa in those with ischaemic heart disease. Ideally, FI_{O_2} should be less than 0.5 and PEEP provided at the lowest pressure consistent with minimizing intrapulmonary shunt and achieving these aims.[74 87]

All victims of near-drowning who are hypothermic should be rewarmed in an ICU with continuous monitoring.[75] Those who are cardiovascularly stable may be warmed slowly but actively, at a controlled rate of approximately 1 °C h^{-1}. This can be achieved using warmed humidified inspired gas, warmed i.v. fluids, warming mattress/blanket or wrapping exposed areas in dry woollen blankets. It is advisable to consider rapid rewarming for any patient whose core temperature is less than 28 °C because of the perilous state of the myocardium and its propensity for ventricular arrhythmias below this temperature. Patients who have an unstable cardiovascular system or are in cardiopulmonary arrest should be warmed more aggressively with consideration given to extracorporeal rewarming (ECR) using haemofiltration or cardiopulmonary bypass (CPB).[47 98]

Methods used to rewarm rapidly without ECR include bladder irrigation, gastric lavage,[85] oesophageal heat interchanger,[57] pericardial lavage, peritoneal dialysis,[85] thoracotomy and pleural lavage.[50] The easiest way to accomplish this in most hospitals is peritoneal dialysis.[85] The dialysate

(2 litre of potassium free) is warmed to 54 °C so that it enters the peritoneal cavity at 43.5 °C, and hourly cycles are preferred.[85]

The advantages of ECR are rapid restoration of normothermia up to 10.7 °C h^{-1},[98] reduction of high blood viscosity found in hypothermia and, most importantly, when bypass is used, there is reinstitution of perfusion regardless of cardiac rhythm[11] with avoidance of "rewarming shock". An additional benefit is the ability to rapidly off-load ultrafiltrate in the presence of overwhelming pulmonary oedema; Norberg and colleagues removed 2300 ml in 1 h to facilitate withdrawal from CPB.[72]

Those in cardiopulmonary arrest

Full resuscitation must be attempted in accordance with the Resuscitation Council (UK) guidelines and an attempt made to rewarm the casualty to 33 °C. This may cause manpower problems when prolonged external chest compressions (ECC) are required. Successful manual massage maintained for a period of 4.5 h has been demonstrated,[90] while Ireland and colleagues reported success after 5.5 h using a "Thumper" cardiopulmonary resuscitator system (Michigan Instruments Inc., Grand Rapids, MI, USA) mechanical device.[47] The advantage of a mechanical device is to ensure consistent effective compression during rewarming thus maintaining an adequate circulation to meet metabolic demands and facilitate regular emptying of the heart during ECR.[47] Jones and Swan also recommend the use of such devices in prolonged resuscitation.[49]

Cardiopulmonary bypass

Rewarming by institution of emergency CPB has been used with dramatic effect in severely hypothermic casualties who were in full arrest,[11 43 47 49 98] many after submersion in cold water.[50 60 72 99] The most notable of these was the neurologically intact survival of a 2.5-yr-old girl who was trapped under ice for 66 min.[11]

The majority of reports describe partial bypass from the femoral artery to femoral vein.[11 43 49 98] Norberg and colleagues described conversion to full bypass to achieve faster flow rates and decompression of a dilating asystolic heart in a 7-yr-old boy with a successful outcome.[72] Letsou and co-workers suggested that full bypass using median sternotomy is the method of choice.[60] There is also a report of successful resuscitation in one of two hypothermic adult casualties using a modified dilatational/Seldinger technique to apply percutaneous CPB via the femoral veins, with a portable pump and paediatric oxygenator.[79] CPB provides fast rewarming of the core, maintains tissue perfusion and oxygenation while assisting the cold and inefficient heart to regain normal electromechanical function.

The advocates of median sternotomy claim that exposure and cannulation of the aorta and right atrium is faster than dissection and cannulation of the femoral vessels in the pulseless patient, and that flow rates are faster. There may also be advantage in having access to the heart for massage, defibrillation and decompressive venting of a cold and dilating ventricle.[60] A survey of members of the American Association of Thoracic Surgeons and the Southern Thoracic Surgical Association in the early 1980s produced evidence of 174 cases of hypothermia rewarmed with CPB with a survival rate of 45%.[60] A review of the literature in 1994[97] analysed data from 68 hypothermic patients undergoing CPB. In reports describing attempted resuscitation of two or more cases the survival rate was 50%; if case reports and singletons were included the rate improved to 60%. VF was associated with greater survival than asystole, but the difference (73% *vs* 52%) was not significant. Walpoth and colleagues also noted that documented VF had a favourable outcome with CPB in hypothermia.[98] Eighty percent of survivors returned to their previous level of function. The recommendations of that review were that CPB resuscitation is advised for hypothermic patients in arrest and for those with core temperatures less than 25 °C, irrespective of rhythm; patients in a stable rhythm of 25–28 °C can be treated with CPB or conventional warming methods.[97] The maxim "nobody is dead until warm and dead" should always be borne in mind.[35]

Cessation of resuscitative efforts

Hyperkalaemia in severely hypothermic patients is usually indicative of asphyxial cardiac arrest before significant cooling occurred.[63] A potassium concentration in excess of 10 mmol $litre^{-1}$ is not compatible with successful resuscitation[39 84] and is advocated for use in the triage of avalanche victims.[12]

Hypoxic encephalopathy is probably the most debilitating of the consequences of near-drowning. The majority of flaccid, comatose victims admitted to the ICU suffer either severe cerebral injury or cerebral death. Early prediction of outcome requires accurate determination of the nature and extent of neurological injury; it is also fundamental for patient management. In children, there are four distinct outcomes: full recovery, neurologically impaired survival, persistent vegetative state and death.[8] Cerebral resuscitative efforts to reverse the changes of hypoxic damage and reperfusion injury have rarely been successful.[66 74] Poor outcomes are especially likely when ICP >20 and CPP <60 mm Hg, despite therapy.[74]

Prognosis

One USA source[14] cited by Orlowski[75] estimated that one-third of all near-drowning survivors were moderately to severely brain damaged. The prognosis for children in the UK appears to be similar: of 188 hospital resuscitations of near-drowning patients reported by Kemp and Sibert,[53] 33 had fixed dilated pupils on admission to hospital; of these 13 died, 10 had severe residual neurological defects (spastic quadriplegia) and 10 recovered fully. A recent report from Seattle[34] found an unfavourable outcome in patients who were comatose on admission: of 72 admissions there were 38 deaths, 14 in a vegetative state, three with dependent neurological impairment, six with mild neurological impairment and 11 discharged normal. The Australian experience was similar: 31 admissions with cardiac arrest of whom 17 died and six survived with severe spastic quadriplegia.[100] This could be related to the warmer waters found in the Brisbane area. This view is supported by the Canadian experience[10] where prolonged in-hospital resuscitation and aggressive treatment of near-drowning victims who initially had absent vital signs and were not hypothermic (>33 °C), resulted either in eventual death or an increase in the number of survivors with a persistent vegetative state.

A prognosis score for paediatric near-drowning victims has been derived by Orlowski.[74] It is based on five indicators: age younger than 3 yr, maximum submersion estimated longer than 5 min, post-rescue delay in resuscitation for greater than 10 min, coma at time of admission to hospital and initial pH less than or equal to 7.1.

Neurological classification of 101 paediatric drowning and near-drowning victims based on the level of consciousness, as assessed by GCS, has been used for prognostic purposes.[19] GCS<5 predicted a high-risk group of patients with 80% mortality or permanent neurological sequelae. In general, 2–6 h after the accident, patients who remain decorticate, decerebrate or flaccid fair poorly; patients who are improving at this time, but remain unresponsive, have a 50% chance of doing well, while those who are showing definite signs of improvement (alert, stuporous or obtunded but responding to painful stimuli) generally do well and most have a normal or near normal outcome.[74] A recent article by Kreis and colleagues[56] suggested that the most accurate method of predicting neurological outcome is by magnetic resonance spectroscopy (MRS): their spectroscopic prognosis index distinguished between good (n=5) and poor (n=11) outcome, with one false negative after a borderline MRS result, and no false positive results (100% specificity).

It is generally agreed that hypothermia is neurologically protective, especially in children, although Kruus and co-workers concluded that a core temperature of less than 30 °C is indicative of prolonged immersion and therefore of more severe brain hypoxia.[58] In reports where rapid reversal of the hypoxic state was achieved, in combination with ICU support, often with ECR and occasionally with control of intracranial pressure (ICP), there was complete or near-complete return of neurological function with time.[11 85 86 102]

Many studies assessing predictive factors have analysed data from near-drownings in warmer waters than are usually found in the UK.[19] Therefore, it may be inappropriate to assess immersion victims using the same criteria, as the presence of hypothermia may offer some cerebral protection.[10]

Complications

In addition to the complications already described (pulmonary oedema, infection, hypothermic cardiac arrhythmia, hypoxic encephalopathy and cerebral oedema), disseminated intravascular coagulation (DIC) has been described in near-drowning,[85] as has rhabdomyolysis.

Rhabdomyolysis complicated by acute renal failure has been reported in two normothermic casualties of near-drowning in cold (14 °C and 17 °C) surf.[2] One victim who was retrieved in cardiopulmonary arrest and was alert, lucid and apparently normal 1 h later, had a plasma creatinine concentration of 2106 μmol litre^{-1} 3 h after immersion. He required support with peritoneal dialysis for 11 days and forced saline diuresis to avert oliguria. The second patient discharged 2 h after the event, re-presented 24 h later complaining of weakness, myalgia and dark urine. His serum creatinine concentration was 359 μmol litre^{-1}, and forced saline/frusemide diuresis avoided the need for dialysis. Excessive or sustained muscle exercise and heat stress are well recognized causes of rhabdomyolysis; cold stress is a significantly less common trigger. However, in view of the potential consequence of acute renal failure, it would seem prudent to measure total creatinine kinase activity in addition to serum electrolytes and simple urinalysis in survivors of near-drowning.

Peripheral neurological sequelae may be manifestations of traumatic or even "non-freezing cold injury" to peripheral nerves rather than hypoxic damage from near-drowning. One should also be mindful of the near-drowning patient having a predisposing injury or medical condition, while the possibility of there being a drug-related condition should also be borne in mind.

Other treatment modalities

Artificial surfactant (Exosurf) has been used successfully in the management of a 9-yr-old victim of near-drowning with a rectal temperature of 30.3 °C who was acidotic (pH 6.95).[62] Despite circulatory and ventilatory support ($F\text{I}_{O_2}$ 1, minute volume 230 ml kg^{-1}, PEEP 5 cm H_2O, peak ventilator airway pressure 40 cm H_2O) acidosis persisted and there was severe and progressive respiratory distress (pH 6.87, Pa_{O_2} 7.6 kPa, Pa_{CO_2} 12.4 kPa, base excess −17.5 mmol litre^{-1}). Four hours after admission artificial surfactant was instilled slowly via the tracheal tube. Within 5 min there was an improvement in gas exchange (Pa_{O_2} 11.5 kPa, Pa_{CO_2} 9.5 kPa) and a decrease in peak pressure to 30 cm H_2O, with no change in ventilator settings. His trachea was extubated 3 days later and he was discharged neurologically intact.

Animal models of near-drowning have failed to demonstrate any improvement in pulmonary function after the use of exogenous surfactant,[47 76] although damage to the alveolar capillary membranes is reduced. This disappointing finding may be a result of using volumes of surfactant which were too large and instilled too soon after injury, causing documented severe hypoxia (i.e. a second major insult). The use of smaller volumes, instilled or nebulized at different times, with additional PEEP, have not been reported.

A study on the effect of corticosteroid therapy on survival and blood-gas exchange in dogs after aspiration of fresh water drowning demonstrated no beneficial effect.[13] Their value in the management of pulmonary injury has not been proved[68] and probably should not be used.[74]

Conclusions

The rapid onset of cerebral hypothermia would appear to be the essential mechanism by which some submerged victims, in particular children, appear to be able to withstand protracted periods of asphyxia without suffering irreversible neurological damage. For this protective mechanism to be effective, brain cooling must be established rapidly, before severe hypoxia occurs. Such rates of cooling are unlikely to be achieved through surface cooling alone, or in combination with the diving reflex. It is postulated that rapid selective brain cooling is achieved through pulmonary heat exchange by repeated flushing of the lungs with cold water during the drowning process before cardiorespiratory arrest supervenes.

Successful treatment depends on speedy recovery and the immediate institution of CPR if indicated. All near-drowning victims, even those who appear to be ostensibly clinically well, should be transferred to hospital for pulmonary screening. Although some successful resuscitations of victims in cardiac arrest who are flaccid with fixed dilated pupils have been reported, the great majority would appear to have a poor prognosis. The prognosis is better for those with profound hypothermia but rewarming may be difficult in the absence of a good circulation. Accordingly, consideration should be given to transferring all profoundly hypothermic patients who are in cardiac arrest to a centre where cardiopulmonary bypass facilities are available, sooner rather than later.

Aspects of resuscitation in trauma

J. P. NOLAN AND M. J. A. PARR

In 1988, the Royal College of Surgeons Working Party Report on the management of patients with major injuries[112] highlighted serious deficiencies in the way trauma patients were managed in the UK.[5] At the end of the same year, in an attempt to improve evaluation of UK trauma services, several hospitals started to contribute data to the Major Trauma Outcome Study (MTOS (UK)).[148] This audit system had been established in the USA by Champion and colleagues in 1982.[26] The first report from MTOS (UK), published in 1992, was based on 2 yr of data from 33 hospitals.[157] Unfortunately, its conclusions echoed those of the Royal College of Surgeons' report 4 yr earlier: "the initial management of major trauma in the United Kingdom remains unsatisfactory". Specifically, the mortality for 6111 patients sustaining blunt trauma and treated in the 14 busiest hospitals was significantly higher than that predicted from a comparable US data set (actual 408 *vs* predicted 295.6; $P<0.001$). Other key findings from this report were: (a) 21% of patients with an injury severity score (ISS) greater than 15 took longer than 1 h to reach hospital, and (b) a senior house officer was in charge of initial hospital resuscitation in 57% of seriously injured patients.

What initiatives have been taken in an attempt to correct these deficiencies in trauma patient management? Has the outcome for seriously injured patients in the UK been improved? This review addresses these questions while covering the following topics: pre-hospital trauma resuscitation, communication, advanced trauma life support (ATLS), trauma teams, airway management, fluid therapy and resuscitation end-points.

Pre-hospital trauma resuscitation

Apart from the severity of injury, probably the single most important factor determining the outcome of a trauma patient is the time interval from the moment the injuries are received to the provision of definitive care. Definitive care for the trauma patient implies achieving a clear airway and effective ventilation, haemorrhage control and restoration of an adequate blood volume.

A recent retrospective study of pre-hospital trauma deaths in North Staffordshire reported that, on the basis of post-mortem evidence, airway obstruction had been present in two-thirds of those patients in whom death was judged not to have been inevitable.[63] Although one can criticize the design of this study, there is a clear message: more bystanders must be trained in simple first-aid and the interval between the time of injury and arrival of the emergency services must be reduced. The authors of this study suggested that first-aid could be tested at the time of the driving test. Current standards for ambulance response times dictate that 50% of all calls are responded to within 8 min and 95% within 14 min (urban areas) and 19 min (rural areas). The ambulance performance standards have been reviewed recently and in the future some form of prioritized dispatch system will be used in an attempt to achieve the new government targets (table 1).[24]

The main controversies in pre-hospital trauma management concern the type of pre-hospital provider and the interventions they perform. In common with the emergency medical services (EMS) in the USA, most of the UK uses a

Table 1 Proposal for prioritized ambulance response times. **An interim target of 75% within 8 min has been accepted for implementation in England from 2000–2001.

Immediately life threatening (category A*)	90%<8 min**
Serious (category B)	50%<8 min 95%<14 min
Not life-threatening or serious	Local decision

*Patients in category A are:

A1. Adults with chest pain associated with any of the following: pallor, cyanosis, shortness of breath, sweating, nausea or vomiting; but specifically excluding those for whom the pain is intensified by breathing.
A2. Individuals who are unconscious, fitting or unresponsive for any cause.
A3. Individuals with severe breathing problems who are unable to speak whole sentences.
A4. Injuries to the head or trunk.
A5. Individuals recognized as having anaphylactic shock.
A6. A woman with severe obstetric haemorrhage.
A7. A child under the age of 2 yr.

paramedic-based system. In other parts of Europe (in particular, France, Germany and Belgium) ambulance technicians are supported by physicians, usually anaesthetists, in mobile intensive care units (MICU). In the UK, ambulance technicians are trained in basic airway management, cervical spine control and shock advisory defibrillation. Paramedics have the additional skills of tracheal intubation, i.v. cannulation, fluid therapy and use of i.v. analgesia.[125] Supplementary skills provided by physicians include: use of neuromuscular blocking drugs and a broader range of analgesia and fluids, insertion of chest drains, cricothyroidotomy and the ability to triage the patient to the most appropriate hospital. In theory, the physician's ability to provide a more sophisticated and individualized continuum of patient care (not necessarily protocol-driven) in the initial hospital phase may expedite definitive care. Unfortunately, there are no randomized, controlled studies proving that the outcome for trauma patients is influenced by the type of pre-hospital provider or even the procedures performed. There are only small, retrospective, observational studies which have produced conflicting results.[73, 10[illegible], 115, 116, 121, 126] Some studies have suggested that ALS procedures improve physiological variables but not outcome.[25] One of the problems with pre-hospital trauma studies is the lack of a uniform system or set of definitions for reporting results. A working group has been convened to develop "Guidelines for uniform recording and reporting of performance and outcome after trauma" very much along the lines of the Utstein template for the reporting of pre-hospital cardiac arrest.[134] It is hoped that this will enhance the ability to compare data derived from different EMS systems.

A prominent American emergency physician stated recently that "despite our beliefs and biases, EMS is enormously over-funded in relation to our current ability to scientifically justify its effectiveness".[128] This dearth of quality data fuels the "scoop and run" *vs* "treat in the street" debate. To address this problem in the UK, the NHS Executive have commissioned the Medical Care Research Unit at the University of Sheffield to carry out an evaluation of the use of paramedic skills in pre-hospital trauma care.[62] This study involves three ambulance services and compares treatment by ambulance personnel with basic life support (BLS) skills only with first response by BLS crew with an ALS crew attending when requested, with immediate attendance by an ALS ambulance crew. The study is in part a retrospective, observational study, and in part a prospective, randomized study. It will assess the cost-effectiveness of ALS skills and their influence on various outcome measures. The results of this study will be presented later this year (S. Hughes, personal communication). In the meantime, except where patients are trapped, it would seem logical to limit interventions at the scene to establishing an open airway and effective ventilation, controlling external haemorrhage with pressure and expediting transport to a trauma centre. For penetrating cardiac injuries, delays of just 15 min in transportation increase morbidity and mortality, and rapid transport with BLS may give the best chance of survival.[47]

PRE-HOSPITAL ADVANCED AIRWAY MANAGEMENT

Airway management of the trauma patient in the pre-hospital setting is fraught with difficulties. As yet, there is no perfect method. The ideal would be a simple technique that provided effective ventilation, with little risk of gastric insufflation, and which did not have adverse cardiovascular effects in hypovolaemic or head-injured patients. While tracheal intubation remains the gold standard for airway management, it is often an unrealistic expectation in the pre-hospital setting. Pre-hospital personnel must be taught the technique and perform it frequently enough to maintain the skill. They are not able to use neuromuscular blocking drugs, access to the patient may be difficult and being able to see the larynx in strong sunlight can be almost impossible. To compound the problem, the popularity of the laryngeal mask among anaesthetists is limiting the opportunity for paramedics to learn and practice intubation. Are there satisfactory alternatives?

Bag–valve–mask

Bag–valve–mask ventilation with the use of oropharyngeal or nasopharyngeal airways is a difficult skill to master, is best performed by two individuals and has a high potential for gastric insufflation.[7]

Combitube

The Combitube is a double-lumen tube which is designed to ventilate the patient's lungs whether the tube enters the trachea or the oesophagus. It enters the oesophagus in approximately 90% of insertions. Massive inflation of the stomach occurs if ventilation is applied to the incorrect tube, so confirmation of correct placement is essential. The Combitube has been used successfully during cardiopulmonary arrest[43] and has been evaluated by paramedics in the pre-hospital setting[130] but is contraindicated in severe oropharyngeal trauma.

Laryngeal mask airway

The laryngeal mask airway (LMA) allows rapid, effective ventilation with a single operator, with improved oxygenation, less hand fatigue and probably less risk of gastric insufflation compared with bag–mask–valve ventilation.[19] Although the LMA does not completely protect the airway from aspiration, the risk of this has almost certainly been overstated. Furthermore, the significant risk of unrecognized endobronchial, or worse, oesophageal placement of a tracheal tube is often overlooked. From the perspective of ambulance service personnel, the LMA has several advantages compared with the tracheal tube. Training in use of the LMA is quicker and easier than for tracheal intubation[105] and the retention of skills with the

LMA is better; this would overcome some of the training difficulties faced by ambulance trusts.

The LMA protects the upper airway from soiling from above.[69] This is particularly relevant to the trauma patient with maxillofacial injuries in whom the risk of aspiration of blood is greater than the risk of aspiration of gastric contents. In a recent review of severe trauma patients, 15 patients had aspirated before arrival of an ambulance[85]; of these, 12 had aspirated blood, only two had aspirated blood and vomit, and one had aspirated vomit only.

The LMA may be inserted successfully where access to the patient is limited, for example in entrapments. The LMA can be inserted from the front of the patient while the head and neck are maintained in neutral alignment.[49] Insertion of the LMA causes less cardiovascular response[152] and increase in intracranial pressure (ICP) than laryngoscopy or tracheal intubation. Thus the LMA may offer some advantages for head-injured patients where the increase in ICP in response to laryngoscopy and tracheal intubation, and any coughing and straining, contributes to secondary brain injury. An observational study of pre-hospital use of the LMA has been reported from South Australia.[48] Thirty ambulance officers attempted 233 insertions in the field over a 12-month period and achieved 81% success rate. Sixteen of these were in trauma patients.

In the UK, it would seem logical for both ambulance technicians and paramedics to be trained to insert LMA. The LMA provides the technician with a more effective device than the simple Guedel airway, and gives the paramedic a backup should intubation prove impossible.

PRE-HOSPITAL SURGICAL AIRWAY

If a patient has an obstructed airway, and intubation or LMA insertion are not possible, cricothyroidotomy is a life-saving procedure. In many North American states paramedics are trained to perform cricothyroidotomy and apparently achieve this with considerable success. A recent study of 50 cricothyroidotomy attempts in trauma patients by paramedics in Indiana concluded that the procedure was successful in 47 (94%).[67] This is in close agreement with a study of the procedure performed by air ambulance flight nurses in which a surgical airway was established successfully in 68 of 69 patients (98.5%), with an acute complication rate of 8.7%.[18] As yet, paramedics in the UK are not trained to perform surgical airways. One of the main concerns expressed by ambulance service trainers is that the likelihood of any given paramedic having to perform the procedure would be very low, therefore, even if they could be trained they would have a limited opportunity to maintain the skill. Although this is undoubtedly true, the same argument must apply to most anaesthetists, yet we, quite rightly, are expected to perform a surgical airway in an emergency. Physicians on the London Helicopter Emergency Medical Service (HEMS) perform cricothyroidotomy if a secure, patent airway cannot be established by any other means.[156] HEMS doctors attend to particularly difficult (often trapped) trauma cases and are in a unique position to collect data on the pros and cons of pre-hospital cricothyroidotomy.

PRE-HOSPITAL I.V. FLUID MANAGEMENT

Should a severely injured patient be given i.v. fluids before arrival at hospital? This question is at the hub of the most controversial debate in pre-hospital trauma patient management. Many of the issues also apply to in-hospital fluid resuscitation. The two opposing views on fluid resuscitation are discussed in turn, followed by what we think is a rational solution!

Do not give pre-hospital i.v. fluid

Provided that pre-hospital times are short, some would argue that establishing venous access is not a priority, that the procedure is time consuming and that insignificant volumes of fluid are infused before arrival at hospital.[32,73,107,126] Furthermore, in the presence of uncontrolled bleeding, aggressive fluid therapy may be detrimental. On the basis of several animal studies of uncontrolled haemorrhage it was concluded that i.v. fluids increase arterial pressure but also reverse vasoconstriction, dislodge early thrombus, increase blood loss, cause a dilutional coagulopathy and reduce oxygen delivery causing a metabolic acidosis.[10,11,22,76,132] In these animal studies, allowing arterial pressure to stay low until control of haemorrhage was achieved, so-called permissive hypotension, improved survival. A close clinical analogy is the patient with a ruptured abdominal aortic aneurysm. In these cases it has been suggested that fluid resuscitation should be minimal in all but the moribund, and a systolic arterial pressure of 50–70 mm Hg should be maintained until the aorta is clamped.[28] The mortality rate of 23% quoted by protagonists of this approach contrasts markedly with a mortality rate of 70% in aneurysm patients who received vigorous fluid resuscitation before surgery.[68] The laboratory research was transplanted to the clinical trauma arena by Bickell and colleagues.[12] In a prospective, controlled study, patients with penetrating torso injury and a pre-hospital systolic arterial pressure of less than 90 mm Hg received either standard i.v. fluid therapy or underwent venous cannulation but received no fluid until arrival in the operating theatre. Of 289 patients receiving delayed fluid resuscitation, 203 (70%) survived to discharge from hospital, compared with 193 of 309 patients (62%) who received immediate fluid resuscitation (P=0.04). In a more recent analysis of these data, patients were sub-grouped into major vascular injury, solid organ injury, non-cardiac injury and cardiac injury. While there was a trend towards an improved outcome in all groups, the only patients in whom a statistically significant improvement in in-hospital mortality could be demonstrated were those with penetrating cardiac injury.[147a] This study has raised many methodological concerns and several traumatologists[23,124] disagree with the authors' conclusions.

Give pre-hospital i.v. fluid

The opposing view is that fluid resuscitation should be started immediately because the longer the period of hypotension, the greater the risk of complications and death, and that hypovolaemia is the cause of one-third of pre-hospital fatalities.[31] Most clinicians would agree that the conclusions of the study of Bickell and colleagues were obtained under very specific circumstances: all patients were injured within the city limits of Houston, only those with penetrating injuries to the torso were included, the mean age of patients was only 31 yr and pre-hospital times were extremely rapid (mean interval between call and arrival at the trauma centre was 30 min). Furthermore, the authors did not discuss the causes of death or details of airway intervention. It would be unwise to extrapolate the findings of this study to older patients with chronic illness, blunt trauma, those with head injuries or to other EMS systems where pre-hospital times may not be as short. There are problems extrapolating from laboratory animal studies to the human trauma victim. Although in porcine models gut barrier function remains intact and survival is good after prolonged hypotension with a mean arterial pressure of 40 mm Hg, the same may not apply to the trauma patient with complicated multiple pathology.[46 132 140]

There are at least two circumstances where minimal or no pre-hospital fluid resuscitation is likely to be extremely detrimental: patients with head injury and those where pre-hospital times are prolonged. In both of these situations there is little point in delivering the patient for definitive care when they have already received an overwhelming ischaemic insult. The patient will die regardless of the quality of in-hospital resuscitation. Hypoxia or hypotension increases dramatically the morbidity and mortality after severe head injury, and therefore oxygenation and an adequate cerebral perfusion pressure must be maintained at all times.[27 133 147] As cerebral perfusion pressure (CPP)=mean arterial pressure (MAP) − ICP, and assuming an ICP of 20 mm Hg in a patient with a severe head injury, MAP of at least 90 mm Hg needs to be maintained to provide a CPP greater than 70 mm Hg. Hypotension must be treated aggressively to prevent irreversible ischaemia.

Where the pre-hospital phase is prolonged, adequate perfusion of vital organs (especially gut and kidneys) reduces the risk of subsequent multiple organ failure. The gut is a silent organ in the resuscitation setting. Gut perfusion suffers early and may not return despite achieving apparently appropriate resuscitative goals (see resuscitation end-points, below).

A solution to pre-hospital fluid therapy

There is little doubt that the arrival of the trauma patient in the emergency department with venous access secured is an advantage. Attempts at pre-hospital venous cannulation are acceptable provided they do not delay the transfer of the patient to definitive care or distract from maintaining an open airway with effective ventilation and haemorrhage control. Cannulation en route does not add extra time and surprisingly may be as successful as when attempted at the scene.[66 100]

It is difficult to generalize but in most circumstances fluid resuscitation should be kept to the minimum required to maintain a viable outcome for vital organs until definitive control of haemorrhage has taken place. What is the minimum for any given patient and how can this be assessed in the difficult pre-hospital environment? Should we accept a relatively low arterial pressure. Sustained hypotension of less than 70 mm Hg for more than 30 min correlates with a mortality of 60%,[151] yet allowing a systolic pressure of 50–70 mm Hg in arteriopaths with ruptured abdominal aortic aneurysms produced very good results.[28] In reality, trauma patients represent a spectrum of pathology and what is ideal treatment for one is inadequate for another. Ideally, we should differentiate between uncontrolled and controlled haemorrhagic shock. In uncontrolled haemorrhagic shock control of bleeding has not occurred, haemorrhage is ongoing and aggressive i.v. fluid therapy is likely to increase bleeding. Rapid surgical control of haemorrhage is the priority; sufficient fluid resuscitation to ensure viable survival should be given until haemorrhage is controlled. The great difficulty comes in the translation of these ideals into procedures that can be followed by ambulance personnel. How does the paramedic know which trauma patient has uncontrolled haemorrhage and which does not. Ambulance services are very aware of current thoughts on trauma patient management and are already striving to reduce pre-hospital times. The Staffordshire Ambulance Service NHS Trust strongly encourages its paramedics to insert i.v. cannulae en route, rather than at the scene, unless the patient is trapped. Furthermore, fluid therapy is targeted to maintaining a radial pulse only (C. Carney, personal communication).

When the patient has received definitive care and haemorrhage has been controlled, the goals of resuscitation shift to optimization of oxygen delivery (see below). In clinical practice separation of these two phases may be indistinct because continued haemorrhage may not be definitively controlled by surgery alone and the ischaemic insult before haemorrhage control may determine long-term outcome.

Communication

Communication is vital in providing an efficient link between pre-hospital and in-hospital trauma patient resuscitation. The importance of having advanced warning before arrival of a severely injured patient in the accident department cannot be overstated. Ideally, the ambulance officer at the scene should be able to communicate directly with accident department staff via a talk-through link. This provides concise and essential information on the patient's condition and the estimated time of arrival at hospital. Accident department staff can then decide whether to alert individual specialists or, if it exists, the trauma team. Many hospitals have specific criteria for a trauma team call. With advance warning, medical and nursing staff can prepare a resuscitation bay for the patient's arrival.

In-hospital resuscitation

ADVANCED TRAUMA LIFE SUPPORT

A considerable advance in trauma patient resuscitation has been made by the introduction of the advanced trauma life support (ATLS) in the UK in the latter half of 1988.[96] Unfortunately, this is very difficult to prove and only one group has documented a reduction in trauma mortality after the introduction of ATLS.[34] The ATLS course manual and slides are produced by the Committee on Trauma of the American College of Surgeons (ACS).[135] By its very nature, the course is didactic and an identical core content is taught to all doctors on ATLS courses across the world. Not unexpectedly, this has led to a certain amount of criticism, particularly from British anaesthetists.[9] For example, earlier editions of the ATLS manual strongly promoted blind nasal intubation, a concept that was never accepted by UK anaesthetists.[153] The UK ATLS Committee has had some influence on later versions of the manual and the approach to these controversial areas has been rationalized. ATLS provides a useful framework on which we can base our resuscitation efforts. Although the course is aimed at the single-handed physician working in a rural hospital, the ATLS procedures can be adapted easily for a team approach. It is testament to the perceived use of ATLS that since its introduction to the UK more than 9000 individuals have attended a provider course and there are now 621 ATLS instructors (O. Egerton, personal communication). Incidentally, in the UK, anaesthesia is represented by more ATLS instructors than any other specialty. More information on ATLS can be received from the ATLS office, Raven Education Department, RCS (tel. 0171 973 2102, fax 0171 973 2117, E-mail atls@rcseng.ac.uk).

The ATLS course focuses on the initial management of patients with major injuries during the so-called "golden hour". Donald Trunkey has described previously the trimodal distribution of trauma patient deaths.[139] The first peak of death is within seconds to minutes of injury (e.g. severe head and chest trauma) and only measures to prevent trauma will reduce it. The second peak of death, the early deaths, are those dying, for example, from intracranial haemorrhage and multiple injuries with hypovolaemia; timely and appropriate resuscitation of these patients should reduce mortality. The third peak of death represents those patients dying, a few weeks later, from sepsis and multiple organ failure. Appropriate management of the patient in the resuscitation phase, with rapid restoration of cellular oxygenation, should also reduce this third peak of deaths. The classic "trimodal" distribution of trauma patient deaths has been challenged recently,[117 155] but this should not detract from the philosophy of rapid, systematic and appropriate management.

Table 2 Composition of a typical trauma team

- Team leader—primary and secondary surveys, co-ordination of team, overall responsibility for the patient while in the A&E department.
- Anaesthetist—airway, ventilation, central venous access, difficult peripheral access, fluid balance, analgesia
- Other doctor—all other procedures, chest drain, fracture splintage, urethral catheter
- Nurses x 2—measure vital signs, record data, remove clothes, assist doctors.
- Radiographer—cervical spine, chest and pelvic x-rays, other x-rays as requested by team leader.
- Porter—to take samples to pathology labs, to retrieve urgent blood from blood bank.

Table 3 The role of the trauma team leader[99] (reprinted with permission)

- To offer advice to any hospital wishing to discuss or refer a patient, and to accept appropriate referrals
- To obtain a history from the ambulance staff (for direct admissions) or from the referring doctor and medical escort (for transferred patients)
- To examine the patient (performing primary and secondary surveys)
- To establish the priorities for investigation and intervention
- To co-ordinate the trauma team
- To maintain an overview, avoiding undue involvement in practical procedures, but intervening appropriately in critical situations.
- To supervise the administration of fluids, blood and blood products.
- To provide analgesia
- To request and interpret investigations in conjunction with other team members
- To consult with or refer to other specialists where appropriate, indicating any perceived needs for urgent intervention
- To supervise spinal precautions
- To supervise the patient during transfer within the hospital and during imaging procedures
- To co-ordinate the assignment of the consultant responsible for continuing care
- To arrange transfer to the operating theatre, intensive care unit or other ward area (or to another hospital when indicated), and to provide a detailed hand-over to their staff
- To review the patient subsequently to help maintain continuity
- To inform the family
- To excuse the trauma team members at the end of the resuscitation, and to debrief the team after difficult cases
- To make a detailed note in the patient's records and to record agreed information for audit.

THE TRAUMA TEAM

Trauma patient resuscitation is most efficient if undertaken by a team of appropriately trained doctors and nurses.[35] In this way a variety of tasks can be undertaken simultaneously, a process known as "horizontal organization". The precise composition of the team inevitably varies from one hospital to another. The composition of a typical team and the team members' roles are listed in table 2. The role of the team leader is particularly important and has been defined comprehensively by a British

Table 4 The primary survey

1. Airway with cervical spine control.
2. Breathing with ventilatory support
3. Circulation and haemorrhage control
4. Disability—a rapid assessment of neurological function
5. Exposure—while considering the environment, and preventing hypothermia

Trauma Society Standards Working Party (table 3).[99] These standards represent the ideal and are probably achievable only by hospitals with relatively large trauma units. Nevertheless, many hospitals have worked hard to create a system that brings senior, experienced clinicians into the trauma resuscitation room before, or soon after, admission of a seriously injured patient.

PRIMARY SURVEY AND RESUSCITATION

The initial resuscitation of the trauma patient entails the primary survey, simultaneous resuscitation and identification of those injuries that require immediate surgery. The aim of the primary survey is to look systematically for immediately life-threatening injuries, in the order that they are most likely to kill the patient (table 4). If life-threatening problems are detected they are treated immediately, before proceeding to the next step of the primary survey. A head-to-toe examination of the patient is not undertaken until the patient's vital signs have been stabilized.

Airway and cervical spine

Every patient sustaining significant blunt trauma, particularly above the clavicles, should be assumed to have a cervical spine injury until proved otherwise. These patients should have the cervical spine immobilized with a semi-rigid cervical collar and bilateral sandbags or blocks joined with tape or straps across the forehead (fig. 1)[106] or by manual in-line stabilization (MILS). If the patient has an unstable cervical spine injury, further movement may cause or worsen injury to the cord. Thus all airway manoeuvres must be performed carefully, and without moving the neck.[6 15 30 55 86 141] The cervical spine cannot be deemed undamaged until the patient has been examined by an experienced clinician *and* appropriate radiological procedures have been completed.[154] A reliable clinical examination cannot be obtained if the patient has sustained a significant closed head injury, is intoxicated or has a reduced conscious level from any other cause.

In the unconscious patient, or in the presence of haemorrhage from maxillofacial injuries, the airway is best secured by placing a cuffed tube in the trachea. Other reasons for intubating the trachea of a trauma patient during the resuscitation phase are to improve oxygenation and control ventilation, and to allow appropriate procedures to be performed on uncooperative patients. For example, in the case of the combative, intoxicated trauma patient with head and other potentially severe injuries, induction of anaesthesia and intubation facilitate definitive investigation (e.g. CT scan) and prevent secondary injury (self-inflicted trauma and secondary brain injury from hypoxia, hypercapnia, hypotension and hypertension). There is increasing evidence that, if performed with care, tracheal intubation of a patient with a cervical spine injury carries relatively little risk.[30] However, uncontrolled intubation in a patient with an unstable cervical spine injury can result in serious damage to the spinal cord.[53] Thus a sensible approach to airway management of patients with known mechanisms of injury is to initially treat all of them as if they had an unstable cervical spine injury, even if the initial plain films are normal.[131]

The technique of choice for emergency tracheal intubation in a patient with a potential cervical spine injury is direct laryngoscopy and oral intubation with MILS, after a period of preoxygenation, i.v. induction of anaesthesia, paralysis with suxamethonium and application of cricoid pressure (fig. 2).[29 152] Placing the patient's head and neck in neutral alignment tends to make the view at laryngoscopy

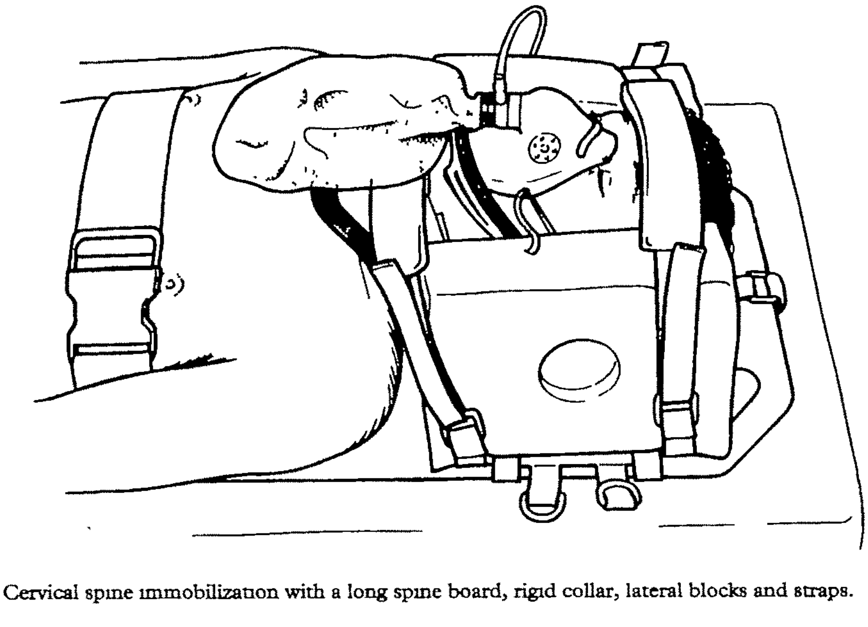

Figure 1 Cervical spine immobilization with a long spine board, rigid collar, lateral blocks and straps.

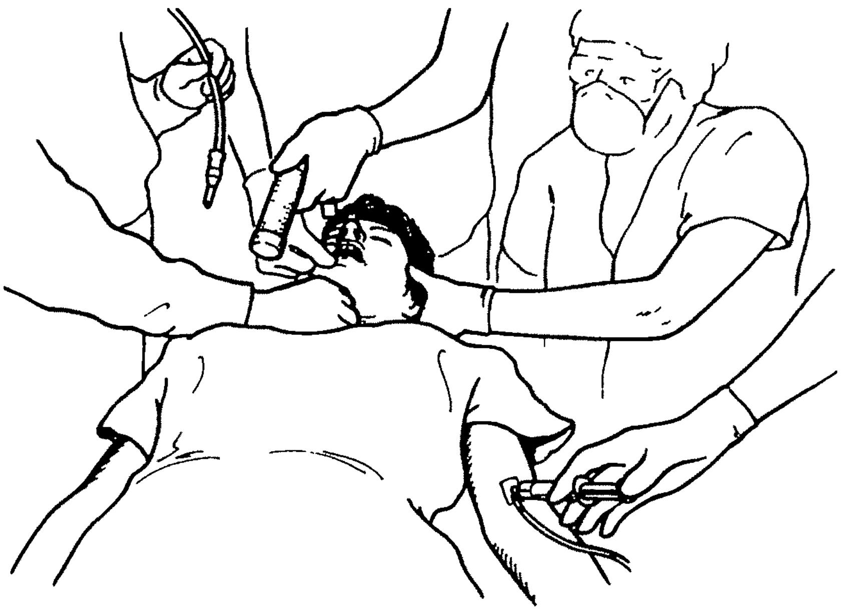

Figure 2 Rapid sequence induction of anaesthesia and manual in-line cervical stabilization in an acute trauma patient.

worse,[54] but intubation is aided greatly by the use of a gum-elastic bougie.[57 97] If intubation of the patient's trachea proves impossible, a laryngeal mask[49 104] may provide temporary oxygenation and ventilation while surgical cricothyroidotomy is performed.

Smooth induction of anaesthesia and neuromuscular block provide optimal conditions for intubation in high-risk patients. All anaesthetic induction agents are vasodepressors and respiratory depressants, and have the potential to produce or worsen hypotension. There is no evidence that the choice of induction agent alters survival in major trauma patients. Their appropriate use during resuscitation involves careful assessment of the clinical situation and thorough knowledge of their clinical pharmacology. The safest strategy is for the anaesthetist to use agents with which he or she is familiar; the trauma resuscitation room is not the place for experimentation. Major trauma patients are at significant risk of awareness.[16] Anaesthetic requirements need to be judged, as always, on an individual basis and the risk of awareness kept to a minimum. Severely injured patients requiring intubation generally fall into three groups: (a) patients who are stable and adequately resuscitated; they should receive a standard or slightly reduced dose of induction agent, (b) patients who are unstable or inadequately resuscitated but require immediate intubation; they should receive a reduced, titrated dose of induction agent (in this situation factors such as best guess, skill and experience come into play), and (c) patients who are in extremis, and are severely obtunded and hypotensive; here induction agents would be inappropriate but neuromuscular blocking agents may be used to facilitate intubation. As soon as adequate cerebral perfusion is achieved, anaesthetic and analgesic drugs should be administered.

Suxamethonium retains its status as the neuromuscular blocker with the fastest onset of action, and remains the first choice blocker for intubation of the acute trauma patient. The concerns that suxamethonium may cause an increase in ICP in severe head-injured patients appears to be overstated provided adequate anaesthesia is provided.[20 75] Rocuronium is almost as fast in onset and is favoured by many trauma anaesthetists.[84] In the US, before the availability of rocuronium, vecuronium was a popular choice for use in acute trauma patients.[98]

Circulation

After arrival in hospital, failure to maintain an effective circulation remains the leading cause of death in severely injured patients.[59]

I.v. access. Severely injured patients require at least two large-bore i.v. cannulae. If peripheral placement of these cannulae is impossible percutaneously, other options include: cut-down on a peripheral vein, percutaneous femoral cannulation, central venous cannulation or the intraosseous route. Cut-downs have few complications and can be performed quickly with minimal training. Possible cutdown sites include: the antecubital fossa, saphenous vein at the ankle and proximal saphenous vein. Most anaesthetists are more familiar with the Seldinger technique for placement of large bore cannulae and this choice is supported by a multicentre, prospective, randomized study comparing i.v. access by saphenous cutdown with percutaneous femoral cannulation.[150] In a total of 78 trauma patients, the mean time for cut-down (5.6±2.6 min) was significantly longer than that required for percutaneous femoral cannulation (3.2±1.2 min). The main disadvantage of the percutaneous femoral approach is that it requires a palpable femoral arterial pulse. Internal jugular or subclavian access is preferred by many anaesthetists but central venous access may not be easy in the hypovolaemic patient and there is a risk of creating a pneumothorax. If the central route is used, a 8.5-French gauge pulmonary artery introducer sheath is ideal for rapid fluid resuscitation.

The intraosseous route[118] (usually via the proximal tibia) is useful in children but, using conventional fluids, does not allow high enough flow rates for effective fluid resuscitation in adults. However, there is a possibility of infusing hypertonic intraosseous fluids in adults.[79]

Fluid warming. All i.v. fluids should be warmed properly. A high capacity fluid warmer, such as the Level 1,[21 95] is required to cope with the rapid infusion rates used during trauma patient resuscitation. Hypothermia (core temperature less than 35 °C) is a serious complication of severe trauma and haemorrhage.[82] The aetiology of hypothermia in the patient requiring massive transfusion is multifactorial and includes exposure, tissue hypoperfusion and infusion of inadequately warmed fluids. In trauma patients hypothermia correlates with survival; those with a core temperature decreasing to less than 34 °C have a 40% mortality compared with a 7% mortality for those whose lowest recorded core temperature is 34 °C or above.[71] Hypothermia has several adverse effects:

- the oxyhaemoglobin dissociation curve is shifted to the left, thus impairing peripheral oxygen delivery in the hypovolaemic patient at a time when it is most needed
- shivering may compound lactic acidosis which typically accompanies hypovolaemia and this may be aggravated further by decreased metabolic clearance of lactic acid by the liver
- it contributes to the coagulopathy accompanying massive transfusion.[102] The likely mechanisms involved include: retarding the function of enzymes in the clotting cascade[111] enhanced plasma fibrinolytic activity[103]; and reduced platelet aggregation.[142] Recent studies have shown that bleeding time and prothrombin time, in particular, are prolonged by hypothermia.[101 129 143]

Care must be taken with some of the more powerful warming and rapid infusion systems. There is a potential for rapid circulatory overload unless patients are monitored appropriately and continually.[52]

Principles of fluid management emphasize that restoration of intravascular volume should be fast and efficient. Recognizing that anaemia is tolerated better than hypovolaemia allows the initial fluid resuscitation to be non-blood. While the choice of fluid may be less important than the speed and adequacy of volume replacement, the increasing variety of fluids available tends to confuse the issue. Resuscitation fluids currently available include: isotonic crystalloids (sodium chloride, Hartmann's solution, Ringer's lactate solution), hypertonic saline with or without a colloid component, gelatin solutions (polygeline, succinylated gelatin), etherified starch solutions (hetastarch, hexastarch, pentastarch), dextrans and blood. Haemoglobin solutions are undergoing clinical studies and will be available in the near future.

Colloids vs crystalloids. The crystalloid *vs* colloid debate continues and for reasons discussed below, is unlikely to be resolved. As an increasing number of colloids become available, the controversy may evolve into which colloid *vs* crystalloid.[138] There are some areas of agreement between the opposing views. Most agree that colloids are more efficient in that equivalent intravascular volume expansion is achieved with less colloid. Colloids are more expensive than crystalloids. There is no risk of anaphylaxis with crystalloids. Colloid oncotic pressure is better maintained with colloid. Fluid overload is bad for the patient regardless of the type of fluid used. The amount of interstitial oedema is dependent on the volume of fluid given and there is a negative correlation between a positive fluid balance and survival in critically ill patients.[90] As it takes 2–6 times the volume of crystalloid compared with colloid to maintain the same haemodynamic state in critically ill patients,[64] it is not surprising that crystalloid fluid resuscitation causes greater interstitial oedema. In theory, interstitial oedema has several adverse effects:

- cerebral: obtunded conscious level
- pulmonary: impaired gas exchange
- myocardial: reduced compliance
- tissue: impaired wound healing
- gut: reduced absorption and enhanced bacterial translocation

Despite these reservations, no prospective, randomized studies have demonstrated clearly the superiority of colloids over crystalloids for trauma resuscitation. Double-blind studies with the power to define any advantages are unlikely given the complexity of trauma cases and the difficulty in establishing matched controls. There is also great difficulty in deciding the most appropriate endpoints for such studies. Should it be survival or duration of hospital or ICU stay, or the incidence of organ failure? Other variables, such as age, ISS and pre-injury pathology, are inevitably greater discriminators of outcome than the choice of resuscitation fluid.

Crystalloids. The American College of Surgeons' ATLS committee recommends the use of lactated Ringer's solution for the initial resuscitation of severely injured patients.[135] The use of normal saline may cause a hyperchloraemic acidosis and may compound any underlying pathological acidosis.[83] Part of the rationale for using crystalloids is that trauma patients have sustained considerable interstitial fluid losses and intravascular loss. An alternative explanation is that gelatin solutions are not available in the USA, and alternative colloid solutions such as starch and albumin would be expensive or limited by the volume that can be infused.

Gelatin solutions. Gelatins are the only cheap colloid available that can be infused in unlimited volumes, they have no effects on the cross matching of blood and act as an osmotic diuretic. While it has been suggested that in comparison with saline, fluid resuscitation with gelatin solution prolongs bleeding time,[40 87] the case is far from proved and further study is required.

Hydroxyethyl starch solutions. Hydroxyethyl starch solutions are synthetic polymers derived from amylopectin. Different degrees of substitution of hydroxyethyl groups for glucose result in solutions of varying properties. HES 450/0.7 has an average molecular weight of 450 000 Da and a high molar substitution ratio (0.7). This solution has a long half-life (more than 24 h) and results in prolonged haemodilution. The fact that it accumulates in the reticuloendothelial system has not yet been shown to cause problems. It also causes a coagulopathy via an effect on factor VIII and von Willebrand factor.[72] For these reasons the maximum dose of high molecular weight HES is restricted to 20 mg kg^{-1} day^{-1} and it cannot be recommended for trauma patient resuscitation. Pentastarch (HES 200/0.5) is diafiltered to produce a more homogenous solution (10–1000 kDa) which has a lower weight average and a half-life of approximately 6 h. Animal studies suggest that these medium weight HES solutions may be capable of plugging leaky capillaries in inflammatory states.[146,149,158] Pentafraction (100–500 kDa) is even more homogenous than pentastarch and is the most effective at reducing transvascular leak.[92,109] Hydroxyethyl starch encourages restoration of macrophage function after haemorrhagic shock.[120] A recent study of trauma and sepsis patients showed that 10% HES (200/0.5) resulted in significantly better systemic haemodynamics and splanchnic perfusion than volume replacement with 20% human albumin.[17] Although the medium weight starch solutions appear very attractive for resuscitation from haemorrhagic shock, the fact that they are expensive and can cause anaphylaxis may temper our enthusiasm.[78,93]

Hypertonic saline solutions. Hypertonic crystalloid solutions are attractive as they provide small volume resuscitation and rapid restoration of haemodynamics with laboratory evidence of improved microcirculatory haemodynamics.[79] They exert their effect by recruitment of interstitial volume thus increasing circulating volume and increasing arterial pressure. However, as discussed above, increasing arterial pressure may not always be an ideal goal, and their role in trauma resuscitation has yet to be defined. Many clinical studies are now using small volumes of highly hypertonic solutions (7.5% saline) for pre-hospital resuscitation.[36,89,145] These studies have yet to show a clear improvement in survival as the primary end-point.[77] However, in a subset of head-injured patients with a Glasgow coma scale score of 8 or less, survival to hospital discharge was higher in patients receiving hypertonic saline (with or without dextran 70) compared with those receiving Ringer's lactate.[145] The potential for benefit in head-injured patients is not surprising in that small changes in serum sodium exert much greater effects on serum osmolality, and therefore on brain water and intracranial pressure, than do changes in colloid oncotic pressure.[159] However, hypernatraemia may induce its own problems; administration of large volumes of hypertonic saline to patients with burns resulted in a four-fold increase in acute renal failure and a two-fold increase in mortality.[61]

Blood and haemoglobin solutions. Blood, while being the ideal replacement for haemorrhage, is expensive, in short supply, antigenic, requires cross matching, has a limited shelf life, requires a storage facility and carries a risk of disease transmission. It is well known that blood transfusion has an immunosuppressive effect and one study showed that the volume of blood infused and injury severity score were the only two significant predictors of infection.[2] However, this phenomenon is more likely to be a reflection of the duration and severity of shock.[119]

Having overcome several problems related to toxic stroma, short intravascular half-life and high colloid osmotic pressure, a number of haemoglobin solutions are now at advanced stages of development.[27a,33,70,110] In a rat model of haemorrhagic shock, diaspirin cross-linked haemoglobin (DCLHb) was more effective in restoring tissue perfusion and improving survival than lactated Ringer's solution or 7.5% hypertonic saline.[80] DCLHb has been given to patients undergoing elective abdominal aortic repair[45] and to patients with sepsis syndrome.[113] It has a significant vasopressor effect which is thought to result from binding nitric oxide and from an effect on adrenergic receptors.[122] In 76 human volunteers, genetically engineered haemoglobin (rHb1.1) also produced a transient increase in arterial pressure and studies are underway in anaesthetized patients.[70] The potential for using haemoglobin solutions to resuscitate trauma patients, particularly in the pre-hospital phase, is very exciting. An increase in mean arterial pressure, in conjunction with decreased viscosity of haemoglobin solutions, may result in significantly better oxygen delivery to vital organs. In a rat model of controlled haemorrhage, DCLHb was superior to crystalloid, albumin and blood in gut resuscitation.[42] The potential disadvantages in increasing arterial pressure in uncontrolled haemorrhage (as discussed above) have still to be considered. Furthermore, the long-term safety of massive transfusion with haemoglobin solutions in humans has yet to be demonstrated.

What is the optimal packed cell volume (PCV) in the acute trauma patient? Hypovolaemia is tolerated considerably less well than anaemia. Traditional teaching is that all patients require a PCV of 30% or a haemoglobin concentration of 10 g dl^{-1} for optimal oxygen delivery. However, normovolaemic patients with good cardiopulmonary function tolerate haemoglobin concentrations as low as 7 g dl^{-1}.[94] In a small, randomized pilot study, the mortality of a group of critically ill patients with haemoglobin concentrations maintained at 7–9 g dl^{-1} was no different to a group with concentrations of 10–12 g dl^{-1}.[58] Provided normovolaemia is achieved the reduction in viscosity results in a significant increase in cardiac output[127] and tends to improve tissue oxygenation.[144] The problem is that during resuscitation of the acute trauma patient, a history of ischaemic heart disease or significant respiratory disease may not be available. Furthermore, the haemoglobin concentration of a haemorrhaging patient undergoing resuscitation is changing rapidly. Under these conditions the margin of safety is very small if the haemoglobin concentration is reduced to as low as 7 g dl^{-1} even if the patient is previously healthy. As part of the systemic inflammatory response syndrome, the severely injured patient has an increased oxygen requirement and therefore it would be unwise to chose a "transfusion trigger" on the basis of data that have been obtained from stable anaesthetized patients. Until more data are available from studies on critically ill patients, the haemoglobin concentration of severely injured patient should be targeted at around 10 g dl^{-1} However, in the confirmed cardiovascularly healthy trauma patient with only moderate injuries, a haemoglobin value as low as 7 g dl^{-1} may be acceptable.

Monitoring

By any definition, major trauma patients are critically ill and it is entirely appropriate to provide monitoring in the emergency department which is to the same standard as that in the intensive care unit. Arterial cannulae and central venous catheters should be inserted as soon as possible. Small, portable monitors that display ECG, invasive arterial pressure, oxygen saturation, central venous pressure, end-tidal carbon dioxide and temperature are available widely and should be used in all major trauma patients.

Resuscitative thoracotomy

Resuscitative thoracotomy may be a life-saving procedure. However, it is a high-risk procedure for those individuals involved in resuscitation and should not be undertaken in futile cases. The surgical skill and facility required should be available in the resuscitation area of all hospitals that receive major trauma patients on a regular basis. The indications for emergency resuscitative thoracotomy include:

- control of intrathoracic haemorrhage
- relief of cardiac tamponade
- electromechanical dissociation after penetrating trauma
- uncontrollable haemorrhage below the diaphragm where cross-clamping the thoracic aorta allows haemorrhage control
- control of a massive air leak.

Of 423 patients undergoing emergency thoracotomy, the overall survival rate was 13%.[81] Survival after penetrating injury was 22% (8% survival after gun shot wound and 34% after stab wound) but only 2% after blunt trauma. The authors concluded that emergency thoracotomy is not indicated if there are no signs of life on initial pre-hospital assessment. Although survival from this procedure after penetrating injury is reasonably good, it is rarely beneficial for the victim of blunt trauma.[8,38,60]

Resuscitation end-points

When haemorrhage control has been achieved, the goals of resuscitation are to optimize oxygen delivery and improve microcirculatory perfusion to facilitate the repair process. Patients with severe injuries have high oxygen requirements immediately, and rapidly accumulate a significant oxygen debt, as indicated by high blood lactate concentrations and an increasing base deficit.[37] Shoemaker and colleagues have demonstrated a reduction in mortality in a variety of high-risk surgical patients using therapy targeted to achieve supranormal values for cardiac index (CI) (>4.5 litre min^{-1} m^{-2}), oxygen delivery index ($D\mathrm{O}_2\mathrm{I}$) (>600 ml min^{-1} m^{-2}) and oxygen consumption index ($\dot{V}\mathrm{O}_2\mathrm{I}$) (>170 ml min^{-1} m^{-2}).[123] More recently, investigators have examined the potential benefit of goal-directed therapy, specifically in trauma patients.[13,14,91] There is little doubt that failure to achieve supranormal values of $D\mathrm{O}_2\mathrm{I}$ and $\dot{V}\mathrm{O}_2\mathrm{I}$ is a strong predictor of multiple organ failure and death,[14,91] while the standard haemodynamic measurements of MAP and CVP fail to differentiate between survivors and non-survivors.[14] What we really need to know, however, is whether we can improve outcome by striving to achieve these goals. A recent study in patients with predominantly penetrating injuries showed that mortality can be reduced by targeting the following resuscitation goals: CI>4.5 litre min^{-1} m^{-2}, $D\mathrm{O}_2\mathrm{I}$ >670 ml min^{-1} m^{-2} and $\dot{V}\mathrm{O}_2\mathrm{I}$ >166 ml min^{-1} m^{-2}.[13] This approach to the trauma patient requires insertion of a pulmonary artery floatation catheter and some authors have suggested that this should be placed early in the resuscitation process.[1]

Recent evidence has suggested that aggressive efforts to increase $D\mathrm{O}_2\mathrm{I}$ in critically ill patients may be detrimental.[56] Another study of goal-directed therapy in a group of predominantly trauma patients failed to show any difference in the incidence of organ failure or death.[39] The current popular approach to fluid resuscitation of severe trauma patients is to increase $D\mathrm{O}_2\mathrm{I}$ with appropriate fluid resuscitation and moderate doses of dobutamine (up to 20 μg kg^{-1} min^{-1}), while monitoring mixed venous oxygen saturation ($S\bar{v}_{\mathrm{O}_2}$), base deficit and/or blood lactate concentration.[88]

Several investigators have criticized the use of global oxygenation indices to detect the presence of tissue dysoxia and a recent consensus conference has addressed these issues.[137] It is possible to have regional ischaemia that would not necessarily be reflected by a change in $\dot{V}\mathrm{O}_2\mathrm{I}$ or plasma base deficit.[50,51] The splanchnic bed is the first region to be rendered ischaemic during shock, and after resuscitation is the last to have perfusion restored to normal. Gastric mucosal pH (pH_i) is monitored using a gastric tonometer[41] and correlates well with intestinal oxygen consumption and hepatic venous $P\mathrm{O}_2$, lactate and outcome.[34] pH_i may be a better resuscitation goal in trauma patients than $D\mathrm{O}_2\mathrm{I}$ and $\dot{V}\mathrm{O}_2\mathrm{I}$.[65] The standard technique of gastric tonometry using a saline-filled balloon is rather laborious and allows only intermittent measurement of pH_i; partly for this reason it is infrequently used in clinical practice. New developments in gastric tonometry allow continuous measurement of pH_i either from an air-filled balloon connected to a modified capnometer ("capnometric recirculating gas tonometry") or by directly measuring luminal $P\mathrm{CO}_2$ with a fibreoptic $P\mathrm{CO}_2$ probe.[44,74]

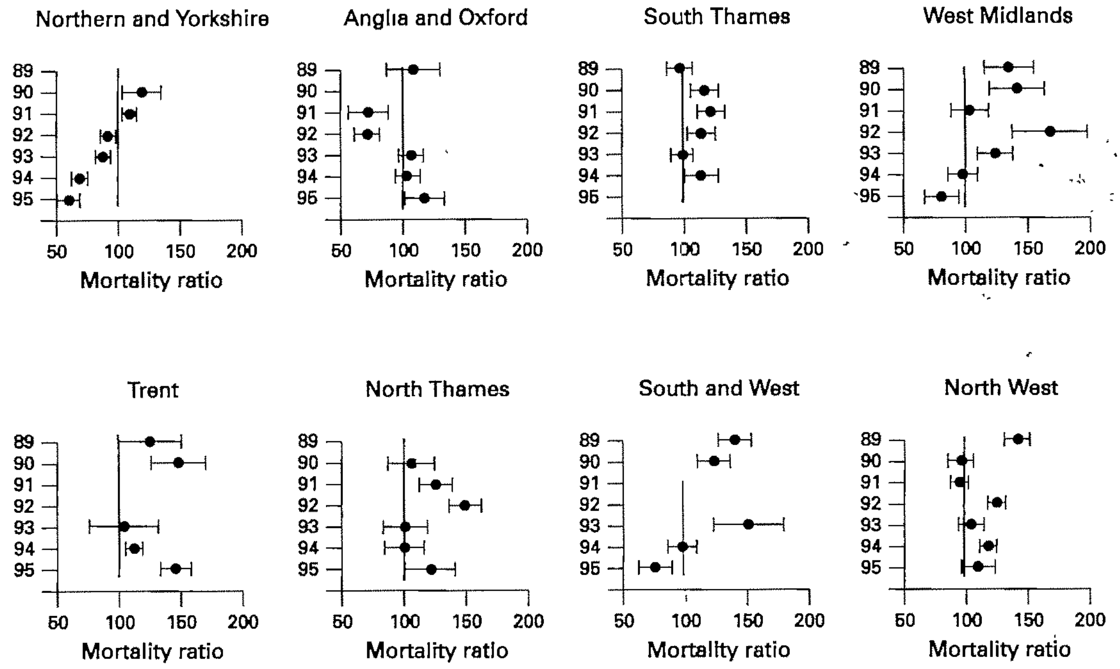

Figure 3 Mortality ratios (±1 SEM) for major trauma patients from 1989 to 1995, by region. Reproduced with kind permission from Maralyn Woodford, National Co-ordinator for the UK Trauma Audit and Research Network.

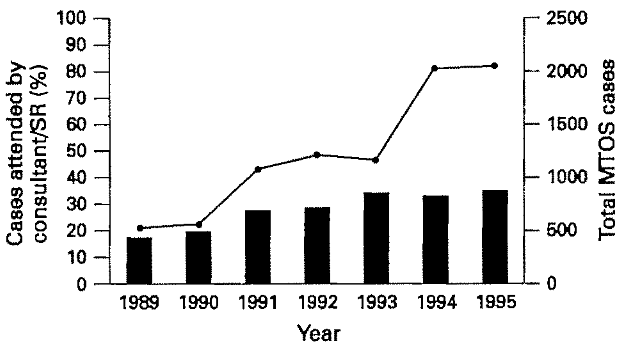

Figure 4 Proportion of severely injured patients seen first by consultants or senior registrars (columns) and total number of cases from the Major Trauma Outcome Study (MTOS) (line), by year. Reproduced from data provided by Maralyn Woodford, National Co-ordinator for the UK Trauma Audit and Research Network.

The UK Trauma Audit and Research Network

The Major Trauma Outcome Study (MTOS) (UK) has been collecting data on seriously injured patients for 8 yr. There are 86 000 patients on the database and 117 hospitals in the UK have enrolled with MTOS.[136] Last year MTOS (UK) changed its name to the UK Trauma Audit and Research Network and formed links with the Cochrane Centre and the NHS Centre for Reviews and Dissemination. It is hoped that this will facilitate the development of evidence-based guidelines for the management of major trauma. On the basis of the data collected so far, MTOS participating hospitals have good cause for optimism. Between 1988 and 1996 the overall mortality ratio (the observed number of deaths divided by the expected number of deaths x 100) has improved from 124 to 97 (fig. 3). Over the 7-yr period 1989–1995, after severity of injury is controlled for, the odds of death in children and young adults (less than 24 yr) after severe injury declined by 16% a year.[114] It is not possible to identify with certainty which of the many facets of trauma patient management have contributed to this apparent improvement in outcome. However, it is likely that developments in assessment and resuscitation techniques, many of which have been discussed above, are major factors. One certain fact is that the proportion of seriously injured patients seen first by consultants or senior registrars has increased from 17% in 1988 to 30% in 1995[136] (fig. 4). In the context of the debate on pre-hospital trauma management, it is of some concern that pre-hospital times have increased from a mean of 37 min in 1988 to 58 min in 1995. Bearing in mind that during this period there was no change in the number of trapped patients or in the distribution of injury severity, we must establish the specific effect of this trend on outcome. Perhaps the Medical Care Research Unit pre-hospital study[62] will provide some answers.

The International Trauma Anaesthesia and Critical Care Society (ITACCS)

In 1988 a group of enthusiasts in Baltimore established ITACCS. The society holds an annual symposium, numerous seminars, offers research grants and has been responsible for several publications on trauma anaesthesia and critical care. More than 1000 members from 44 countries exchange and develop ideas on all aspects of trauma anaesthesia, resuscitation and critical care. Information on the society can be obtained from ITACCS World Headquarters, PO Box 4826, Baltimore MD 21211 USA (Fax +1 410 235 8084).

Conclusion

Several deficiencies highlighted by the 1988 Royal College of Surgeons Working Party Report on the management of patients with major injuries have been addressed and there is some evidence that developments in trauma patient management have improved outcome. The principles outlined above provide the basis for making rational decisions in trauma resuscitation. There is no substitute for training, experience, good communication and team work if resuscitation of the trauma patient is to be completed rapidly and effectively. Trauma continues to be the most common cause of death in the first four decades of life and as part of a multidisciplinary team, the trauma anaesthetist must strive to reduce this mortality.

Uniform reporting in resuscitation

W. F. DICK

Over the past 20 yr resuscitation medicine has become a scientifically recognized interdisciplinary part of acute medicine. However, the two main areas of resuscitation medicine—cardiopulmonary–cerebral resuscitation (CPCR) and trauma life support (TLS)—are still practised under entirely different conditions and circumstances. As a result, data on quality of care, quality of outcome and life after survival, in addition to many other criteria, differ from publication to publication.[7 8 19 24 26 29]

In 1974 the American Heart Association (AHA) published the first edition of "standards for CPR".[1] Many changes were made to subsequent versions of the standards, later to be termed guidelines, because a considerable number of conclusions made in 1974,[1] 1980,[2] 1986[3] and 1992[4] had never been scientifically proved. This was because uniform criteria had not been established to describe the study design of animal and human CPR research projects, to report the characteristics of the emergency medical services (EMS) systems and outcome data.

Consequently, the CPR Research Committee of the European Academy of Anaesthesiology (EAA) met in 1986 to discuss and develop recommendations for animal research in CPR; these were published initially in 1988,[14] followed by a revised version in 1990.[15] Recommendations for clinical CPR studies[15] were published by the same group later that year.

The topics for animal research discussed by the committee included: type of animal; anaesthetic technique; methods of induction and duration of cardiac arrest; CPR technique; ventilation volumes; use of buffers, inotropes and antiarrhythmic agents; and monitoring.

The following topics were included in the recommendations for clinical studies: prospective, randomized studies; patient data; distinction between witnessed and unwitnessed cardiac arrest, and cardiorespiratory and cardiocirculatory arrest; out-of-hospital and in-hospital arrests; VF/VT, asystole and EMD; drugs and routes of administration; monitoring; level of training of responders; pre-arrest conditions; survival after different intervals (outcome); quality of life after survival.

These reports, together with similar initiatives by experts from the American Heart Association,[1 2 3 19 20] European Resuscitation Council (ERC), Heart and Stroke Foundation of Canada (HSFC), Australian Resuscitation Council (ARC) and Resuscitation Council of South Africa (RASC) were the background for an informal gathering by experts from these organizations at Utstein Abbey on the Norwegian Island of Mosteroy in the summer of 1990. At this meeting it was decided to hold a scientific conference on the subject of developing guidelines for uniform reporting of data from cardiac arrest.[11]

The Utstein Consensus Conference was convened near London later that year and members of the organizations participating in the first Utstein symposium were invited. A template was developed to include the most relevant factors for describing and comparing CPR research results. This template was described as the Utstein style after the site of the initial meeting.

Uniform reporting of data—the Utstein style

The term Utstein style has been incorporated into the following templates:

- a template for out-of-hospital resuscitation[8]
- a template for paediatric resuscitation[32]
- a template for in-hospital resuscitation[9]
- a disaster medicine response research template[30]
- a template for reporting laboratory research in animals.[22]

In 1995 Spaite and colleagues[28] reported the results of the US Prehospital Emergency Medical Services Data Conference which provided the basis for an 81-item uniform data set. It was hoped that documentation conforming to this template would answer the question, "has the EMS (apart from out-of-hospital cardiac arrest and resuscitation) had an impact on morbidity and mortality of emergency patients (trauma, intoxication, asthma, myocardial infarction, etc).

Another template for uniform reporting of data after trauma is under development and others may follow.[16 17]

(*Br. J. Anaesth.* 1997; **79**: 241–252).

Key words
Heart, resuscitation. Complications, cardiac arrest. Records, Utstein template.

UNIFORM REPORTING OF DATA AFTER OUT-OF-HOSPITAL CARDIAC ARREST

Terminology

The working group initially focused on developing a uniform and worldwide acceptable terminology set down in a "glossary of terms".

The *glossary of terms* begins with a definition of a cardiac arrest and its aetiology (cardiac, non-cardiac). It also outlines major signs and symptoms, regardless of how long they may persist.

A consensus was established as to what was to be included under the headings basic life support (BLS), advanced life support (ALS), basic cardiopulmonary resuscitation (BCPR) and advanced cardiopulmonary resuscitation (ACPR). The following definitions relating to the treatment of cardiac arrest were agreed.

BCPR includes expired air inflation of the lungs with and without airway adjuncts and face shields (excluding the use of bag–valve–mask devices, laryngeal mask airway, oesophageal tubes/Combitubes or tracheal tubes) and application of external thoracic compression. In the USA, in contrast with European practice, BLS includes knowledge of public access to the EMS system and an educational programme, in addition to technical skills in BCPR

ACLS and ACPR are very similar and include intubation, defibrillation and medication. Defibrillation may become part of BLS in several countries in the future, particularly to take into account the increasing use of automatic external defibrillators (AED).

A distinction was made on the basis of the qualification of initial CPR providers to differentiate between bystander CPR performed by lay responders compared with professional first responders who are either part of the emergency medical system (EMS) or acting as a bystander.

Times, events, intervals

Precise definitions of events, times and event-to-event intervals were made. Some of this information was deemed essential (core data); other data were considered optional (supplementary data). The following example indicates the relationship between events, times and intervals (figs 1, 2).

CARDIAC ARREST

Collapse occurs

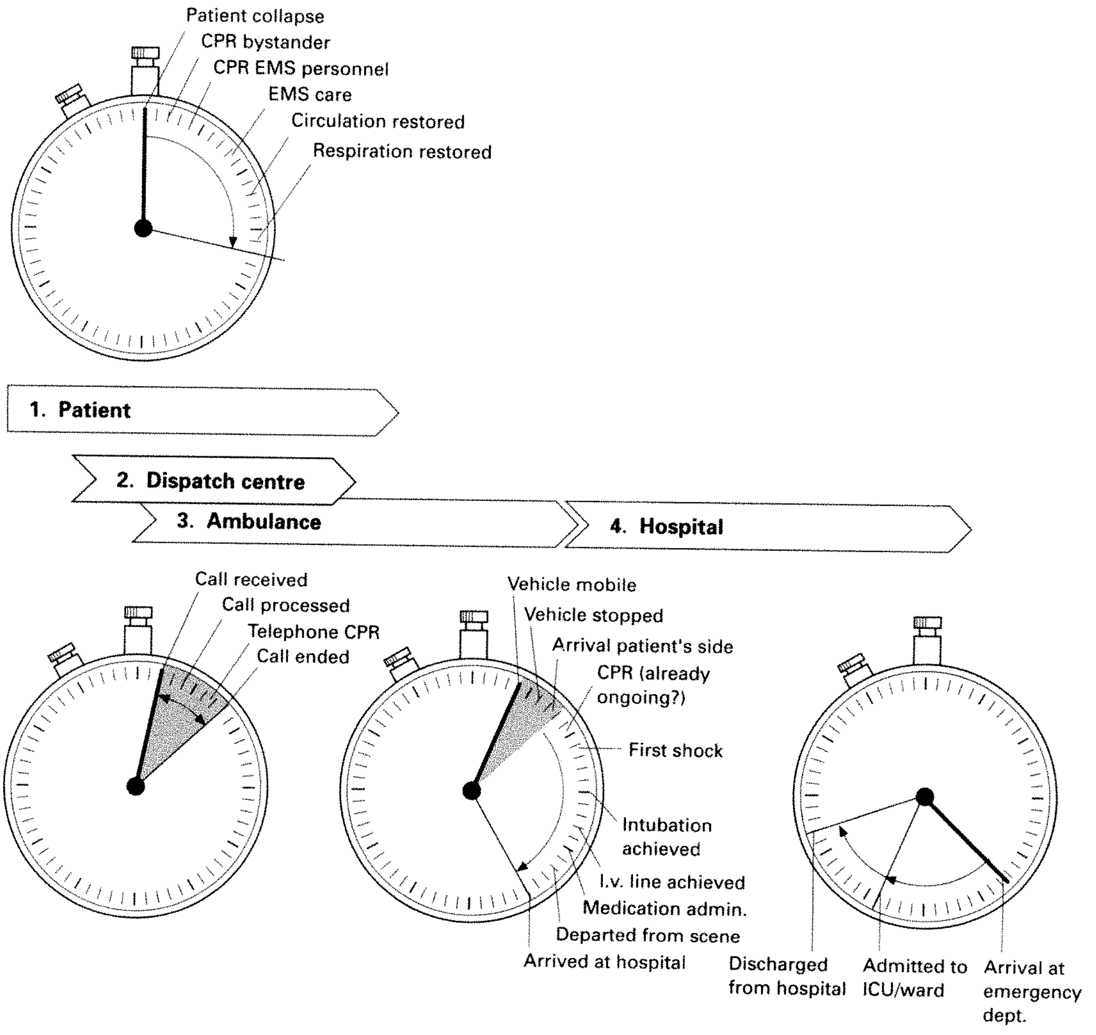

Figure 1 The four clocks of sudden cardiac arrest (reproduced from Chamberlain and colleagues[8] with permission).

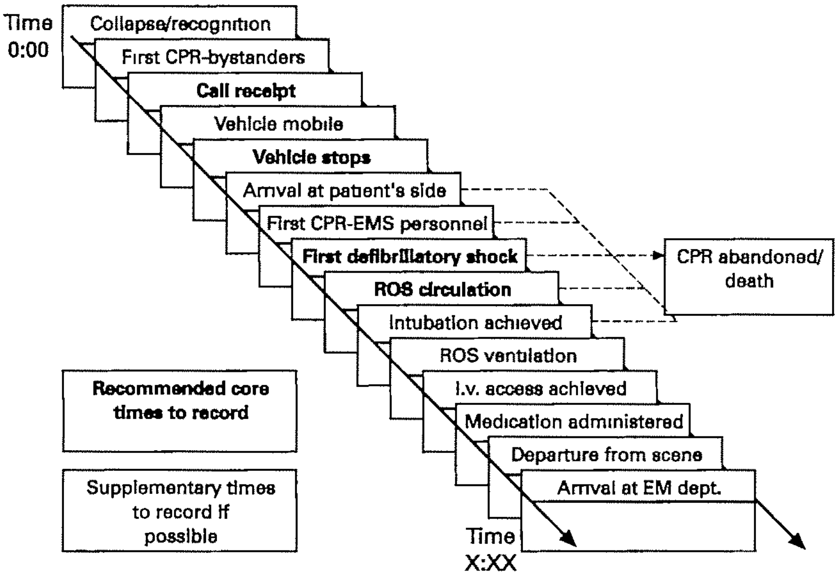

Figure 2 Events associated with out-of-hospital cardiac arrest resuscitation attempts (reproduced from Chamberlain and colleagues[8] with permission).

Collapse to cardiac arrest–recognition interval

Collapse witnessed/recognized.

EMS called
Time of call receipt
BLS starts by bystander
Call processed
First vehicle mobile
Call–response interval.

Arrival of the first ambulance at the scene
Call–arrival interval
Arrival of the first team at the patient side
Call to patient contact interval
BLS continued by professional responders

Arrival of the second tier at the scene
Arrival of the second tier at the patient side.

ALS starts with defibrillation, intubation, i.v. access, medication.
Call to defibrillation–intubation–medication interval

Time of restoration of spontaneous circulation (ROSC)
Call to ROSC interval
Time of departure from the scene
Scene interval
Time of arrival at the emergency department (ED)
Call to ED interval
= Total pre-hospital interval (or time)

Before the introduction of the Utstein template, many events and intervals were frequently not recorded or were confused (e.g. the call–arrival interval was almost always used synonymously with the call to patient contact interval, although the difference between the two intervals may be in the order of 5 min).[7]

Structure of the EMS system

The structure of the emergency medical services (EMS) system is of crucial importance. The initial intervals are determined by the structure, quality and efficiency of the EMS. The template provides an accurate description and classification of the EMS response based on core and supplementary data collected at the dispatch centre (who does what, how and when, and how well?).

Epidemiological and outcome data

In addition to developing a template for uniform reporting of events and intervals it was considered essential to evolve a template for obtaining data on survival, survival rates and quality of life after survival. The template allows description of the population served by the EMS, including information on age, sex, education, socioeconomic status, total number of deaths, incidence of ischaemic heart disease and deaths per 100 000 of the local population (only rarely available). Also included are definitions of confirmed arrest and recommendations as to when resuscitation should or should not be attempted, replacing traditionally used terms such as do not resuscitate (DNR) with do not attempt to resuscitate (DNAR).

Differentiation between initial VF/VT or asystole is important with regard to outcome. The rhythms of electromechanical dissociation (EMD) or pulseless electrical activity (PEA) are still only poorly defined.[9]

A large number of the terms referred to above can be used to describe outcome, for example ROSC at the scene, during transport or on admission, survival to admission to the ICU, general ward, rehabilitation unit or discharge from hospital, survival after cardiac arrest for 6 months, 1 yr, etc. However, information on survival rates alone is inadequate because it does not describe the quality of life after survival. To provide additional data on quality of life at discharge or after survival for 1 yr, the Utstein template recommends the use of the Glasgow–Pittsburgh outcome categories, overall performance categories (OPC) and cerebral performance categories (CPC), although other systems may be used for this purpose.

Forms for uniform reporting of data from out-of-hospital cardiac arrest

To complement the Utstein meeting, a form for uniform reporting of data from out-of-hospital and in-hospital cardiac arrest[13] was prepared and published by a working group consisting of representatives of the ERC, EAA and the Belgian Society for Emergency and Disaster Medicine. The form facilitates the use of the Utstein template.

Publication policy

The Utstein template recommends that publications on CPR should follow the Utstein style to overcome the present confusion arising from the lack of a uniform terminology and general agreement on data to be recorded.

Comment

Several prospective, randomized, comparative, controlled studies in the pre-hospital setting have been performed according to the Utstein style. Most investigations were designed to evaluate the efficacy of new methods of CPR compared with traditional CPR (ACD–CPR, Vest–CPR, etc).

Although it is becoming increasingly apparent that the Utstein template offers an excellent description of the course of resuscitation, from occurrence of cardiac arrest to survival or death under various conditions, there is still a lack of accurate information on the underlying disease. The Utstein template does not differentiate between cardiac arrest caused by electrophysiological disturbances occurring in a young patient or an extensive myocardial infarction in an older patient with coronary artery disease and major myocardial dysfunction.

While the Utstein template provides information on survival and quality of pre-hospital and in-hospital care for these patients, it does not permit conclusions to be drawn on the overall efficacy of the selected treatment. While the use of a resuscitative technique or drug may be highly effective in a young patient with an electrophysiological disorder, it may prove ineffective in an older patient with a malfunctioning myocardium.

UNIFORM REPORTING OF PAEDIATRIC ADVANCED LIFE SUPPORT: THE PAEDIATRIC UTSTEIN STYLE[32]

This "statement for health professionals" was developed by a task force from the American Academy of Pediatrics, American Heart Association and European Resuscitation Council who found that the original Utstein template for reporting adult out-of-hospital data was unsuitable for paediatric use.

Data are presented on the high morbidity, mortality and poor outcome rates in infants and children requiring resuscitation and emphasize the need for guidelines based on scientific evidence, although the latter are only rarely available.

Glossary of terms/dictionary of terms

The paediatric Utstein template, in common with the Utstein template for adults, addresses the problem of a uniform terminology in the "dictionary of key terms" and continues with recommendations for core and supplementary data.

In addition to existing definitions for resuscitation, EMS, cardiac arrest and respiratory arrest, the paediatric Utstein template introduces the term "respiratory compromise" to define ineffective breathing requiring assisted ventilation in infants and children at risk of developing cardiac arrest after respiratory insufficiency.

"Bradycardia/poor perfusion" requiring basic CPR is another term which is different from the adult template. It applies to infants and children with organized cardiac electrical activity but with a low output and low perfusion, usually with heart rates less than 60 beat min^{-1}.

The paediatric template also distinguishes between sustained (>20 min) and intermittent (<20 min) return of spontaneous circulation (ROSC) and introduces the term "return of spontaneous ventilation" (ROSV).

The template includes "times and time intervals", but creates an interval not included in the adult template, the "start–stop CPR interval", that is the time from initiation of CPR to either ROSC or termination of efforts.

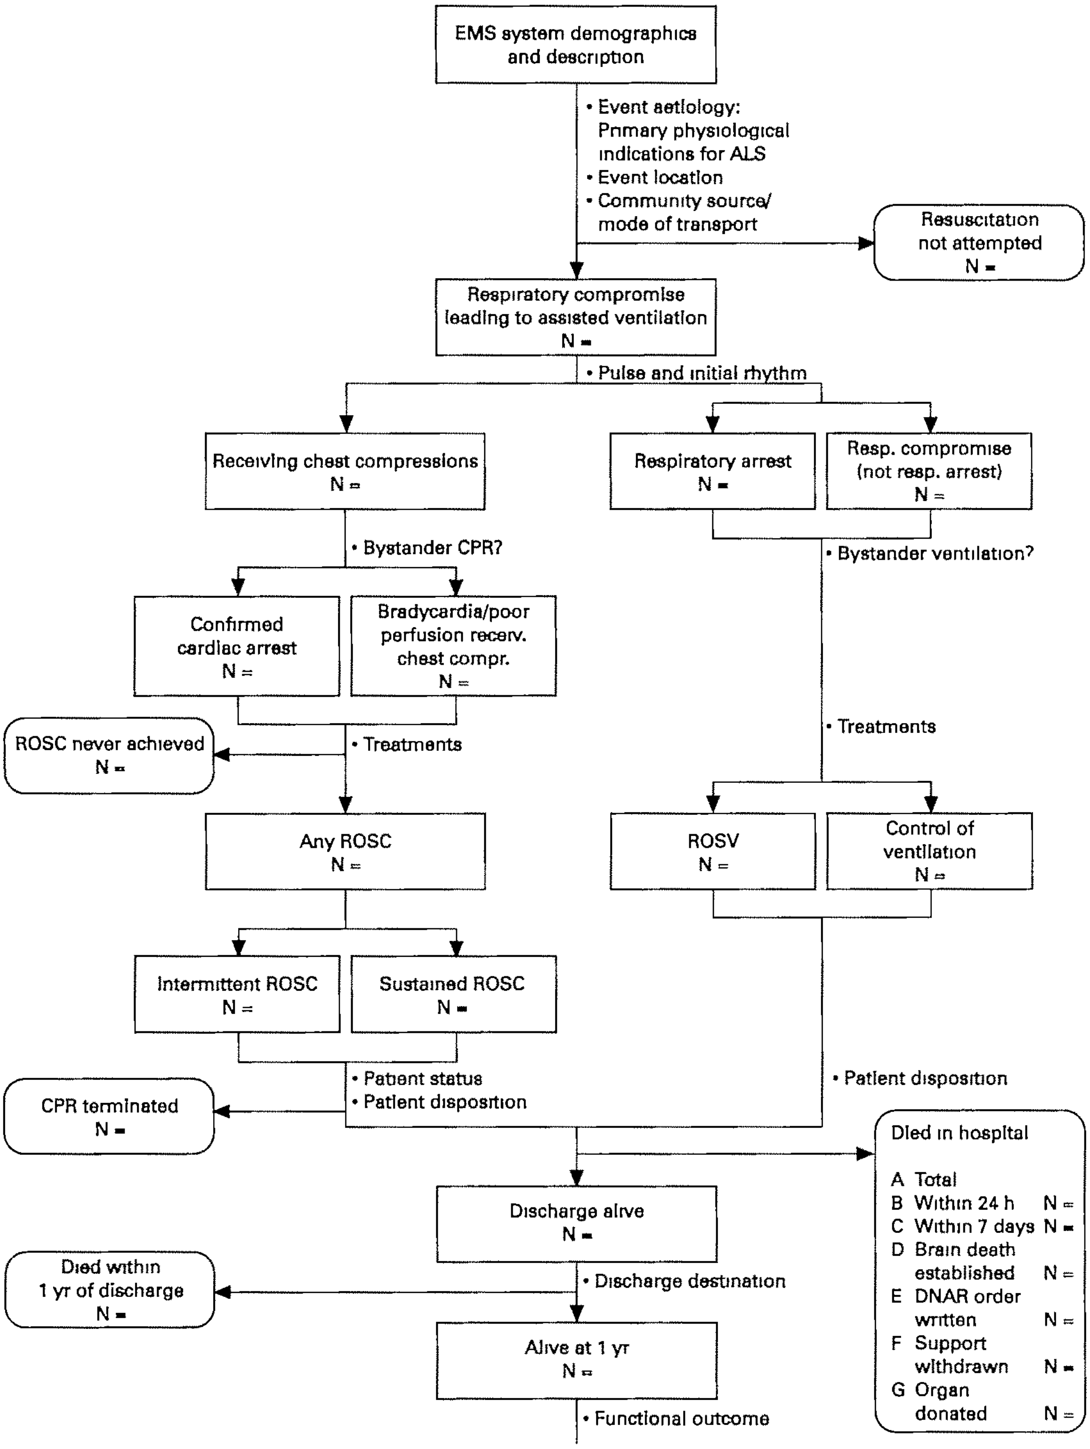
With a view to outcome, the paediatric template defines the return to pre-event conditions as the main goal of all resuscitative attempts. Further emphasis is placed on the importance of investigating efficiency and effectiveness. Of the available systems for measuring quality of outcome, only a modified version of the Glasgow–Pittsburgh outcome categories, with the added category "mild disability group", is recommended for measuring the quality of outcome in infants and children. Although factors such as OPC, CPC and length of ICU stay are considered in the "paediatric risk of mortality score", it fails to record the infant's or child's pre-event conditions. Another, although not yet validated, criterion for measuring quality of outcome may be "time to awakening or return to consciousness".

Reporting of ALS data

In accordance with the adult template, a template for uniform reporting of advanced life support (ALS) has been developed for infants and children to obtain data on epidemiology, aetiology, location of event, etc.

Patient data

Various denominators and numerators have been recommended to calculate the incidence of a wide variety of criteria (fig. 3). The following age groups have been established: 0–12 months, 1–4 yr, 5–12 yr and 13–18 yr. The patient characteristics section of the template discusses the division of the paediatric population into children and adolescents,



EMS system demographics and description
• Event aetiology: Primary physiological indications for ALS

• Functional outcome

Figure 3 Paediatric Utstein style template (reproduced from Zaritzki and colleagues[32] with permission).

recommending the use of the term "child" for individuals up to 13 yr of age and "adolescent" for those aged 13–18 yr. For patient data purposes, anyone less than 19 yr of age is included in the paediatric population.

Influence of the EMS system

The impact of an EMS system on the outcome in paediatric age groups has never been documented sufficiently. This may be because in contrast with adult populations with a high incidence of VF/VT there is an absence of a predominant diagnosis in this age group. Few investigations have been performed on events such as near-drowning or trauma, for example, to provide adequate data to determine the influence of the EMS on paediatric outcome. It was therefore considered essential to include the same EMS system data as in the adult Utstein template.

Hospitals

In contrast with the adult template, the paediatric template recommends a description of the hospital to which the infant or child is transferred (children's or general hospital, number of beds, classification, trauma level, ED, number of ED patients per year, etc). Unfortunately, hospital data have not been included in either the initial or updated version of the Utstein I template. However, in addition to quality of primary care provided by the EMS, quality of care in the hospital itself may influence outcome decisively. In common with the description of the EMS, the description of the hospital should include data on quality of hospital personnel, level of training, personnel responsible for resuscitation, intensive care units, emergency departments, etc.

Events, primary care, patient status at different levels

The paediatric template provides further opportunities for the description of aetiology, location, type of cardiac arrest and quality of initial care. In addition to the recommendations in the adult template for reporting aetiology, the inclusion of information as to whether or not the event resulted from respiratory or circulatory compromise or was caused by cardiorespiratory failure, has been suggested. In addition, classification of the underlying disease according to ICD 9 has been recommended. Concomitant diseases or conditions which may influence outcome should also be reported. It should be stated if the event occurred at home, on the street, at school or work, or in a transport vehicle. Events occurring during inter- or in-hospital transfer or in the ICU should be recorded separately.

Other items which are reported slightly differently in the paediatric template include the pre-event clinical status, clinical status before arrival of the first EMS provider, pre-event monitoring, witnessing of the event, "resuscitation not attempted" information and initial rhythm and pulse.

Diagnosis of supraventricular tachycardia (SVT) in infants and children requires a heart rate of more than 200 beat min^{-1}, which may be difficult to differentiate from sinus tachycardia. The diagnosis of bradycardia requires a heart rate of less than 60 beat min^{-1}.

The level of response to stimulation is assessed by the AVPU scale (*a*lert and responsive, responsive only to *v*erbal stimulation, responsive only to *p*ainful stimulation and *u*nresponsive).

As with the adult template, deaths in hospital are categorized as follows: deaths within 24 h or deaths between 1 and 7 days, related to the total number of deaths. For survivors, the discharge location (home, etc) is recorded. Outcome is defined according to paediatric cerebral and overall categories at all times after discharge.

Unresolved problems include the age at which a child becomes an adolescent or adult (14 or 16 yr?), definition of trauma centres, aetiology, pre-existing morbidity, neurological function after the event, neurological outcome, etc.

Refinements of the document will be published in updated versions of the statement and comments are invited from those involved in paediatric resuscitation.

UNIFORM REPORTING OF DATA FROM IN-HOSPITAL RESUSCITATION: THE IN-HOSPITAL UTSTEIN STYLE[9]

As with the out-of-hospital situation, the efficiency of in-hospital-resuscitation is not based on solid scientific evidence. Data available from retrospective reviews and from the prospective British Resuscitation Study (BRESUS) demonstrate that at 24 h after in-hospital cardiac arrest, survival ranges from 3 to 59%, and from 3 to 27% at discharge.[31] However, this information is influenced by many variations in definitions and procedures of reporting.

The in-hospital cardiac arrest template presents definitions of, for example, what precisely is a cardiac arrest (cessation of cardiac mechanical activity confirmed by the absence of a detectable pulse, unresponsiveness and apnoea or agonal gasping). In contrast with the out-of-hospital situation, however, a hospital patient may be unresponsive or apnoeic because of controlled sedation or anaesthesia. In addition, the co-morbidity rate is higher in in-hospital than in out-of-hospital patients.

Four in-hospital Utstein variables (hospital, patient, arrest and outcome factors) influencing outcome after in-hospital cardiac arrest have been identified in the Utstein template (fig. 4).

Patient variables include age, sex, race, socio-economic status, reasons for admission, pre-arrest and co-morbid conditions, severity estimates, ALS interventions in progress at the time of arrest, previous arrests, witnessed or unwitnessed arrests, and location of events.

The following age groups have been identified (differing slightly from the paediatric template): infancy (0–12 months); childhood (1<3, 3–<8, 8<14 and 14<20 yr); adulthood, with subdivisions into 5-yr periods (20<25 yr, etc).

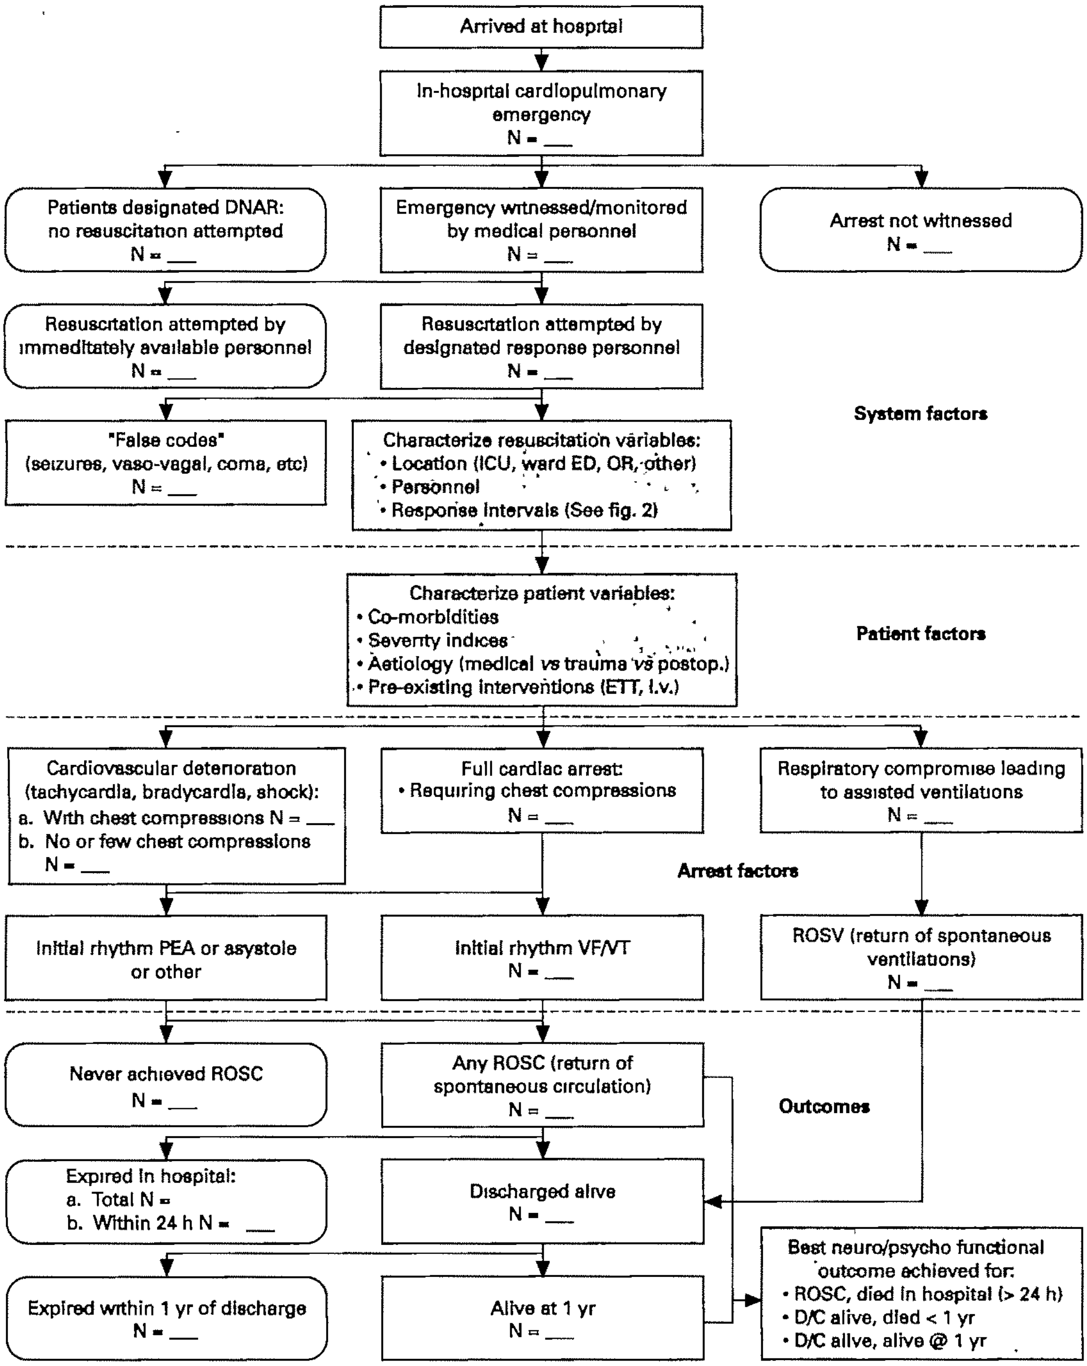
As recommended in the other Utstein templates, pre-arrest capacities should be described according to the Glasgow–Pittsburgh outcome categories, including CPC and OPC (or the paediatric versions).

The definition of co-morbidity is considerably more difficult because the ICD 9 and ICD 9-CM are not used uniformly. Co-morbidity indices may be useful, although only one has thus far been developed for in-hospital purposes.

The severity of a medical condition can be described using APACHE scores for ICU patients, the pre-arrest morbidity score (PAM) or TISS. However, all of these systems are known to be flawed in some respects. Arrest variables comprise rhythms, interventions performed, and event times and intervals.

Event times and intervals are comparable with those in Utstein I but there are some subtle differences. The intervals shown below have been identified as suitable for inter-and intra-hospital comparisons.

Intervals from: cardiac arrest to start of CPR; cardiac arrest to first defibrillation; cardiac arrest to advanced airway management; and cardiac arrest to first administration of medication.



Arrived at hospital
In-hospital cardiopulmonary emergency N = __
Patients designated DNAR: no resuscitation attempted N = __
Emergency witnessed/monitored by medical personnel N = __
Arrest not witnessed N = __
Resuscitation attempted by immeditately available personnel N = __
Resuscitation attempted by designated response personnel N = __
System factors
"False codes" (seizures, vaso-vagal, coma, etc) N = __
Characterize resuscitation variables:
• Location (ICU, ward ED, OR, other)
• Personnel
• Response intervals (See fig. 2)
Characterize patient variables:
• Co-morbidities
• Severity indices
• Aetiology (medical vs trauma vs postop.)
• Pre-existing interventions (ETT, i.v.)
Patient factors
Cardiovascular deterioration (tachycardia, bradycardia, shock):
a. With chest compressions N = __
b. No or few chest compressions N = __
Full cardiac arrest: • Requiring chest compressions N = __
Respiratory compromise leading to assisted ventilations N = __
Arrest factors
Initial rhythm PEA or asystole or other
Initial rhythm VF/VT N = __
ROSV (return of spontaneous ventilations) N = __
Never achieved ROSC N = __
Any ROSC (return of spontaneous circulation) N = __
Outcomes
Expired in hospital:
a. Total N =
b. Within 24 h N = __
Discharged alive N = __
Best neuro/psycho functional outcome achieved for:
• ROSC, died in hospital (> 24 h)
• D/C alive, died < 1 yr
• D/C alive, alive @ 1 yr
Expired within 1 yr of discharge N = __
Alive at 1 yr N = __

Figure 4 In-hospital Utstein style template (reproduced from Chamberlain and colleagues[9] with permission).

Outcome variables include: survival (immediate, short-term and long-term); and quality of life after survival. The quality of life should be assessed using the Glasgow coma score, the Glasgow–Pittsburgh outcome categories leading to the CPC and OPC. The OPC and CPC should be recorded at discharge, and at 6-month and 1-yr intervals. Other recommended outcome criteria are length of hospital stay and costs per survivor.

Hospital variables did not allow accurate categorization, but the different variables are listed in appendix I of this template.

The final section of the template describes the procedure for completing the form (comparable with other templates). Examples refer to:

- Population served (numerators and denominators)
- Explanations of the definitions of a cardiac arrest
- Number of DNAR
- Attempted in-hospital resuscitations (defibrillations, compressions only, airway interventions, combinations)
- False arrests
- Non VF/VT rhythms (see also Utstein I)
- ROSC (intermittent and sustained≥20 min)
  —never achieved ROSC
  —death in hospital (<20 min, >20 min to <24 h, >24 h)
- Re-attempts/re-arrests
- DNAR, support withdrawn, brain dead, organ donation.

Survival figures

One of the most important questions is how should survival be best reported and at what times? The recommendations of the BRESUS study have been adopted.

- Percentage survival from arrest to at least 24 h
- Percentage survival from >24 h to 1 yr
- Percentage survival from arrest to discharge
- Percentage survival from discharge to 1 yr
- Percentage survival from arrest to 1 yr.

However, it is not sufficient that resuscitation is initiated and performed as early as possible, it must also be carried out according to specific quality standards. This gives rise to the question, how is the quality of performance to be rated ?

Apart from haemodynamic criteria (difficult to measure) or pulse oximetry, end-tidal carbon dioxide concentration appears to be the most useful criterion. The pulse check merely confirms whether or not a pulse is present and in many cases may be misleading, as has been shown by our group in a human model[18] designed to simulate cardiac arrest during cardiopulmonary bypass.

The final chapter of the in-hospital template refers to ethical issues in general, informed consent and to the futility of CPR in certain circumstances.

Appendices to the template summarize the following items: data elements; a checklist of information and figures of the template itself, and a standard report form.

With the availability of the widely distributed in-hospital template, it is important to use this template as frequently as possible to determine its value compared with the out-of-hospital version.

Uniform reporting of laboratory CPR research[10 21 23]

"Modern cardiopulmonary resuscitation (CPR) research depends on the use of animal models that are designed to simulate cardiac arrest in humans."[22] This is the introductory statement and guiding principle of the "animal research Utstein style template" which was developed at a conference in Chicago in 1994. Only a few days after the Chicago meeting the proposed guidelines for CPR research were presented and discussed at the Second Congress of the ERC—Resuscitation 94—in Mainz, Germany, with the purpose of "setting guidelines for CPR research".

Consistent with the other Utstein documents, this template begins with a glossary of key terms.

Glossary of key terms

Baseline conditions are described as the "physiological conditions after the animal has been instrumented" but before induction of cardiac arrest. Therefore, these baseline values do not represent true physiological conditions.

Cardiac arrest in an animal model allows a more precise description than cardiac arrest in humans (i.e. VF or asystole, loss of intra-arterial pressure (<25 mm Hg in the aorta), etc).

Ventilation should be reported with consideration of at least two of the following variables: ventilatory frequency, tidal volume and minute ventilation.

Standard CPR. Although this has been established for human CPR, a standard cannot be set for animal CPR because of the wide variety of species, with their differences in size, anatomical configurations, physiology, etc. Thus even though the term "standard CPR" should not be used for CPR in animals, the technique used is to be described meticulously.

Active decompression. Any device used for this technique should be described.

Blood flow. Any method used for measurement of blood flow or regional specific blood flow should be documented.

ROSC. In view of the fact that at least 11 different definitions of ROSC have been proposed, the conference recommended the following definition of ROSC: an aortic arterial pressure of at least 60 mm Hg for at least 10 consecutive minutes (mean, median and confidence intervals).

Survival. This should comprise a minimum of 24 h after resuscitation, including a description of neurological status, multisystem failure, etc.

Intensive care should document any drugs given, at what dosage and how frequently, in addition to any other technical assistance used (defibrillation, assist devices, ventilatory support, etc.)

Intervals and times do not differ from Utstein I.

Experimental events and intervals should be recorded.

Non-intervention intervals. As this is one of the most important intervals and may in itself decide survival or death, it must be described clearly (not in terms of "down time", for example).

An "experimental time line" should provide a graphic description of the above factors (fig. 5).

Induction of cardiac arrest. This is defined as the moment of no blood flow. This cannot be ascertained in cases of asphyxia and exsanguination. In the latter, a pre-selected critical value should serve as the target (e.g. <25 mm Hg)

Compression and release. Phase measurements: during CPR, systolic or diastolic periods cease to exist. Pressures during compression and release should therefore be described.

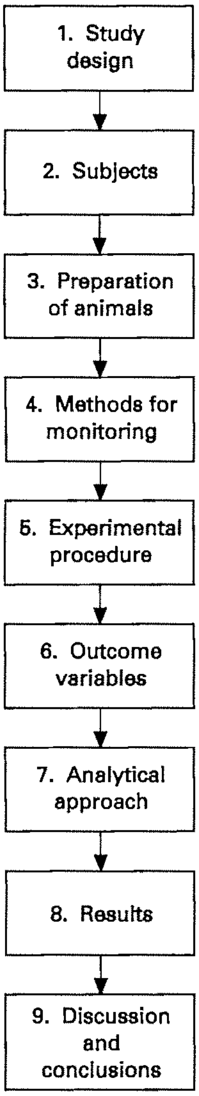
Defibrillation attempt or rescue shock refer to defibrillation during an "experimentally induced episode of VF". Number of shocks, timing and energy should be reported.

Coronary or myocardial perfusion pressure. Coronary perfusion pressure is generally calculated on the basis of simultaneous difference between aortic and right atrial pressure during diastole or the release phase. The method of calculation should be described.

THE ENTIRE TEMPLATE IS DIVIDED INTO NINE SECTIONS

Study design

Consistent with the Utstein I template, it is recommended to distinguish between "essential" or "core



1. Study design
2. Subjects
3. Preparation of animals
4. Methods for monitoring
5. Experimental procedure
6. Outcome variables
7. Analytical approach
8. Results
9. Discussion and conclusions

Figure 5 Reporting template, listing features to describe when reporting laboratory studies on resuscitation (reproduced from Idris and colleagues[22] with permission).

data" and "supportive, useful or desirable data". A prospective study with concurrent control groups is suggested as the optimum study design. The type of blinding needs to be documented where applicable.

Subjects

Physiological conditions need to be targeted for all species and the absence of infections or other diseases. The source of the animals should be reported, and age range, sex, etc. (rats, dogs, swine).

Preparation

Pre-anaesthesia conditions and premedication with sedatives or analgesics, or both, should be reported, and anaesthetic techniques should be described, including doses of drugs used. Maintaining a period of stabilization is essential.

Monitoring

Baseline monitoring includes: heart rate, cardiac output, coronary perfusion pressure; arterial pressure (arterial, mean and cyclic); central venous/right atrial vascular resistances; end-tidal carbon dioxide, arterial and central venous blood-gas analysis and electrolyte concentrations; oesophageal, rectal, PA, VC, bladder or tympanic temperature.

Experimental procedure

An experimental procedure covers the period from induction of cardiac arrest to ROSC or comparable variables of outcome. It cannot be emphasized enough that procedures need to be clinically relevant, for example in VF the non-intervention interval needs to be as close to pre-hospital human conditions as possible (3, 5, 10 min?).

Maintaining minute ventilation constant requires specific types of ventilators; inspired oxygen concentration needs to be documented at regular intervals together with other ventilation variables. Furthermore, information should be provided on synchronization of compression and ventilation. Haemodynamic and blood-gas monitoring, pulse oximetry and end-tidal carbon dioxide measurements should be recorded at regular intervals.

The method of inducing cardiac arrest should be described, in addition to the type of defibrillator used to terminate VF. Energy levels, number of shock attempts and additional medication should be recorded.

Blood flow measurements and changes in blood flow are important factors that need to be recorded (implantable flow probes, microsphere techniques, catheter based techniques).

Outcome variables

In addition to ROSC and the other variables outlined above, short-term and long-term survival are recommended outcome variables. GPCS, OPC, neurological deficit scores and histopathological damage scores have been used to evaluate outcome. It is nevertheless important to bear in mind the limitations of these variables, particularly when applied to animal studies. Cerebral outcome may be calculated on the basis of EEG patterns, EVP patterns and morphological brain investigations.

Statistical methods and publication policies of the respective journals are the topics of the final three sections.

Disaster medical response research: a template in the Utstein style

Although this template is only loosely related to resuscitation, it should be mentioned briefly because it refers to the term Utstein style. In the introductory section of this document the authors draw attention to the fact that there is no uniform methodology for the conduct and reporting of research in disaster responses.[30] In 1995 a meeting was convened at the Utstein Abbey with the purpose of developing a methodology for the conduct and reporting of research in disasters, proceeding in the same manner as for the development of

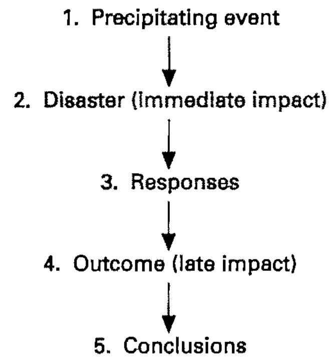


Figure 6 General template used for descriptive evaluations of the medical responses to a disaster (reproduced from Sundness and colleagues[30] with permission).

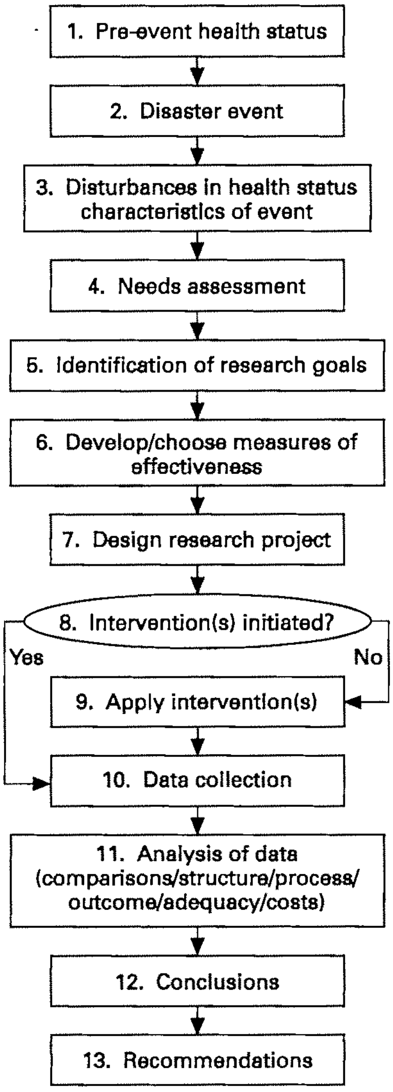
templates for cardiac arrest and resuscitation in adults, infants and animals.

The first chapter of the document attempts to define "What is a disaster?" and specifically "What is a medical disaster?" (fig. 6) before discussing the objectives of a medical disaster response and methods used for medical disaster research. The working group proposed a template for conducting and reporting research in disaster response.



1. Pre-event health status
2. Disaster event
3. Disturbances in health status characteristics of event
4. Needs assessment
5. Identification of research goals
6. Develop/choose measures of effectiveness
7. Design research project
8. Intervention(s) initiated?
Yes
No
9. Apply intervention(s)
10. Data collection
11. Analysis of data (comparisons/structure/process/outcome/adequacy/costs)
12. Conclusions
13. Recommendations

Figure 7 Disaster medicine research template (reproduced from Sundness and colleagues[30] with permission).

The disaster medicine research template provides definitions for: pre-event health status, disaster event, disturbances in health status, characteristics of events, identification of research goals, measures of effectiveness, interventions, data collection, analysis of data, etc. Each of these definitions includes examples of disaster events subdivided according to type, that is natural, human or technological origin, and the character of the onset of the event (sudden, gradual or delayed impact), secondary effects, time and location, scope or magnitude, total population affected, number of refugees and displaced persons, major causes of injury, source, timing and scope of medical assistance, response time (fig. 7), character of responses, public health, early warnings, etc.

Although this template is the result of a discussion by a group of experts, it has never been tested in the field. The first version of the template has been published in *Prehospital and Disaster Medicine*.[30]

The effectiveness of the template must await testing.

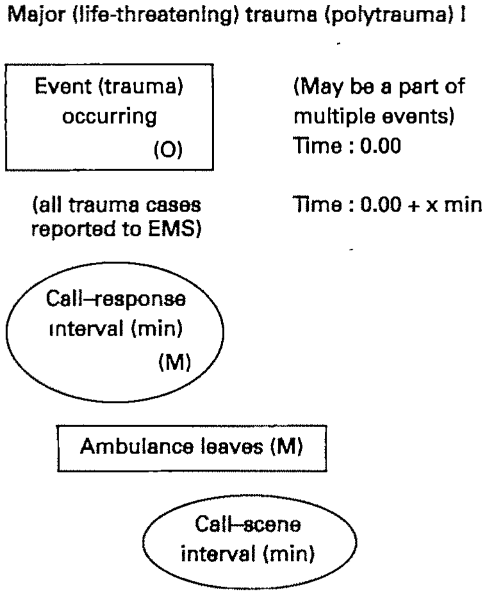
Uniform reporting of data from resuscitation after trauma

Another issue in urgent need of standardization is the pre-hospital care of the trauma patient. At present, trauma patients are treated either via the scoop-and-run or stay-and-play approach[25] by either ambulancemen, emergency medical technicians, nurses/paramedics or emergency physicians, or a combination of these, and transferred to level I–III trauma centres or to hospitals providing different levels of treatment, although they are not recognized as trauma centres.

In 1990 Jones and Brenneis[24] noted that trauma studies could not be compared because of the lack of a prospective, randomized, controlled study design. Similar conclusions were drawn by Spaite and colleagues in 1995[29] emphasizing that the efficiency and quality of trauma care in terms of outcome and quality of life requires the availability of uniform terminology. This terminology has subsequently been developed in the "Utstein style".

The International Trauma Anaesthesia Critical Care Society (ITACCS) and the European Society for Emergency Medicine have recently formed a working group consisting of anaesthetists, trauma surgeons, epidemiologists and emergency physicians. Within the next few months the group expects to complete work on a template for uniform reporting of data after trauma.[17]

Several aspects of the Utstein I template can be used in the trauma template. These include descriptions and terminology defining the emergency medical system, times and intervals. Definitions of major, moderate and minor trauma, multiple injuries, polytrauma, the standard of care in terms of basic trauma life support, advanced trauma life support, scoring systems for the assessment of the patient's general condition and injuries need to be re-designed. The term "standard of trauma care"



Major (life-threatening) trauma (polytrauma) !
Event (trauma) occurring (O)
(May be a part of multiple events) Time : 0.00
(all trauma cases reported to EMS)
Time : 0.00 + x min
Call–response interval (min) (M)
Ambulance leaves (M)
Call–scene interval (min)

Figure 8 Draft template for uniform reporting of data after trauma (reproduced from Dick[17]).

can no longer be accepted as valid in the absence of scientific proof demonstrating that the methods comprising this standard are valid. Certain aspects of care require scientific evaluation, such as fluid resuscitation, airway management and brain protection (fig. 8).[5 6 16 27]

In common with previous Utstein templates, the trauma template needs to define the quality of life after survival following severe trauma (for example 30 days after injury) and the criteria to be used for this purpose (Glasgow coma outcome category, including overall performance categories and cerebral performance categories, major trauma outcome study system, etc).

Summary[12]

The concept of uniform reporting of data in resuscitation has demonstrated its potential value in pre-hospital and in-hospital cardiac arrest in adults, infants and children, in laboratory research, in disaster research and, hopefully, also in trauma care and research.

Ethical aspects of resuscitation

M. MOHR AND D. KETTLER

The current technique of cardiopulmonary resuscitation (CPR), applying expired air ventilation and closed chest cardiac massage, was developed at the beginning of the 1960s. It was an easy-to-learn method which was soon disseminated: "Anyone, anywhere, can now initiate cardiac resuscitative procedures. All that is needed are two hands".[35] Originally developed for the treatment of sudden and unexpected cardiac arrest in supposedly healthy persons, after the first successes this treatment was extended to cardiopulmonary arrest of any origin. CPR is now considered a routine emergency treatment but the reflex-like initiation of CPR has also entailed criticism. In 1985 an editorial in the *Journal of the American Medical Association* stated: "In some way we have wandered from treating sudden unexpected death to practising universal resuscitation".[28] Despite all attempts and modern measures, the majority of resuscitative efforts remain unsuccessful, and only a small minority of patients are returned to their previous health status. Therefore, the appropriateness of CPR procedures has been questioned, especially with respect to individual outcome and patient preference.[3,12,36]

Ethical reasoning in resuscitation

It may be argued that the nature of a resuscitation attempt, demanding immediate and often irreversible interventions, makes ethical deliberation impossible. Even though CPR is an emergency measure, its practice—just as that of any other medical procedure—must be guided by general ethical principles. Beauchamp and Childress have listed four aspects of bioethics to be considered[7]: (1) ethical theories; (2) principles; (3) rules; and (4) particular judgements and actions.

The decision to start CPR is based on a medical judgement that a person is suffering from circulatory arrest. The decision to resuscitate is justified by the moral rule that the victim of a cardiac arrest has the right to be given the opportunity to survive and to receive CPR. The obligation to give aid also belongs to the generally accepted moral rules.

Moral rules are based on ethical principles. Beauchamp and Childress suggest four principles for acceptance as action guides in medicine[7]:

- the principle of beneficence;
- the principle of nonmaleficence;
- the principle of respect for autonomy;
- the principle of justice.

The precise distinction between rules and principles is controversial. Principles are characterized as general and fundamental, and serve to justify moral rules.[7] Rules are related to specific contexts and more restricted in scope. Principles are conceived as binding, but not absolutely binding. This permits each basic principle to have weight without the determination of a ranking.[7] Which principle applies in a case of conflict depends on the unique emergency situation.

Ethical theories represent the integration of principles and rules, depending on individual beliefs and customs.[7] Diverse scientific, metaphysical and religious beliefs may determine the interpretation of a situation and the ethical theory. Ethical theories may serve to justify the principle, the rule and the particular judgement, but they are abstract in nature and may be inapplicable in clinical practice. How might the ethical principles be taken into consideration in clinical resuscitation practice and what might be their consequences?

BENEFICENCE

The principle of beneficence encompasses the fundamental goals of medicine, which are[45]:

- preservation of life;
- restoration of health;
- relief of suffering;
- restoration or maintenance of function.

Modern resuscitation procedures, training of lay persons in basic life support and expansion of effective emergency cardiac care systems have saved many victims from pre-hospital and in-hospital sudden death. The success and beneficence of standardized resuscitation procedures is emphasized by the American Heart Association at the beginning of the Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiac Care: "In the past 30 years, since the introduction of modern

techniques of CPR, there have been dramatic advances in emergency cardiac care of victims with profound circulatory collapse and cardiac arrest. These techniques have restored the lives of many people when breathing has ceased and the heart has stopped beating".[2] Attempts have been made to identify factors indicating a favourable prognosis after resuscitation in the pre-hospital setting in order to provide criteria to facilitate the decision whether to initiate, withhold or discontinue resuscitation attempts.[13 25] The highest survival rate after cardiac arrest occurs when the collapse is observed, when circulatory arrest is caused primarily by cardiac failure with ventricular fibrillation, when lay persons have already applied bystander resuscitation and when professional support arrives at the scene within a very short time.[25]

However, the overall long-term survival rate of 70% reported in the historical article by Kouwenhoven, Jude and Knickerbocker[35] has not been reproduced in more recent investigations. Comparison of different publications on outcome of resuscitation attempts shows an initial resuscitation success in terms of restoration of the circulation of up to 50% (table 1). The proportion of patients who survive after a cardiac arrest to discharge from hospital ranges from 0 to 20%. The results of studies vary, depending on differences in cause and location of circulatory arrest (in-hospital *vs* pre-hospital) and the varying effectiveness of emergency care.

Interviews with survivors of cardiac arrest show that resuscitation and survival are evaluated positively by the majority of patients. Bedell and colleagues[10] interviewed 38 mentally competent survivors of circulatory arrest at the time of discharge from hospital; 21 (55%) said that they would choose to be resuscitated in the future. Follow-up of 28 survivors of cardiac arrest, interviewed 19–43 months after hospital discharge, showed that 89% felt positive about the resuscitation, and 67% would consent to another resuscitation attempt.[42]

NONMALEVOLENCE

Nonmaleficence incorporates the principle of "above all do not harm, or *primum non nocere*".[1] Nonmaleficence implies avoiding anything that might have negative consequences, whereas beneficence means the performance of positive acts to promote good.[7]

In the event of circulatory arrest, the patient is in danger of dying within minutes. Any resuscitation attempt aims at averting death (maleficence) and saving life (beneficence). Can further damage be inflicted by a resuscitation attempt?

Resuscitative efforts are unsuccessful in the majority of cases. In at least in 50% of cardiac arrests, the action of the heart cannot be restored (table 1); another 30% die in hospital after successful restoration of the circulation. For these patients, resuscitation means an extension of the process of dying by hours or days, often without regaining consciousness and accompanied by the concomitants of intensive care treatment, such as tracheal intubation and artificial respiration. This means considerable suffering for the patient and relatives, and is a heavy burden for those involved, including the hospital staff. Of those who survive, approximately 20–50% suffer from neurological disabilities,[23] ranging from slight disturbances of cognitive functions to the "ultimate tragedy" of resuscitation[5] —severe hypoxic brain damage (persistent vegetative state).

Evaluation of survivors of cardiac arrest revealed a decrease in functional status caused by the fear of another cardiac arrest.[10] Others reported that 35% of survivors had a reduced capacity to perform activities in everyday life.[46] These disabilities often resulted in physical dependence on other people (nursing homes); only a small percentage were able to return to work. Altered social contacts were common after the cardiac arrest, with 42% of patients complaining of social isolation.[46]

High survival rates after cardiopulmonary arrest are the exception rather than the rule.[8] Centres reporting their results may indicate a particular interest in emergency cardiac care in these locations. Therefore, these centres might not be representative of all communities or hospitals. Overall survival rates in the USA have been estimated to be only 3–5%.[8]

CPR after trauma is associated with a very poor outcome, with a survival rate close to zero.[15 43] These discouraging results are independent of differences in patient selection and levels of trauma care. Even in physician-staffed pre-hospital trauma care systems, the chance of surviving a post-traumatic cardiac arrest is minimal. The poor results are very

Table 1 Outcome of pre-hospital and in-hospital cardiopulmonary resuscitation in the adult

disappointing considering the generally young age of the victims and the high expenditure which is often required for rescue operations associated with accidents.[15]

The poor survival rates after a traumatic cardiac arrest have lead to discussion of futility in resuscitation. Initiation of CPR is obviously not indicated when there are signs of death, such as post-mortem lividity, rigor mortis or decomposition. Nevertheless, even if these signs are absent, the efficacy of a resuscitation attempt may be in doubt and the aspect of futility has to be considered. For a treatment to be judged futile it must be ascertained that it has no benefit. The benefit of a treatment depends on the outcome of the intervention, the probability of that outcome and the patient's perception of that outcome.[21] There are some situations where efforts to resuscitate appear to be futile with regard to the expected physiological outcome. Unilateral decisions by physicians to withhold or terminate resuscitation based on a medical judgement of futility may be justified[2]:

- in conditions where scientific investigations have demonstrated the ineffectiveness of resuscitative efforts;
- in patients suffering cardiac arrest despite optimal treatment to maintain vital functions (e.g. in progressive cardiogenic shock);
- in patients where appropriate resuscitative efforts have been attempted without restoration of circulation.

These circumstances represent the recommendations of the 1992 American Heart Association conference panel on ethical issues in adult resuscitation. It was the consensus that futility should be strictly defined and that it should represent zero benefit.[21] Using the term futility more loosely involves value judgements which need to be discussed with the patient or his surrogate.[2]

PATIENT AUTONOMY

Physicians do not have the right to treat patients without their consent: *Voluntas aegroti suprema lex.* The right to consent or to refuse is based on the principle of respect for autonomy.[7] Physicians must obtain informed consent from patients before undertaking procedures. The following elements have been proposed as the components of informed consent[7]: (1) competence; (2) disclosure of information; (3) understanding of information; (4) voluntariness; and (5) authorization

The process of informed consent from a competent patient involves adequate disclosure and understanding of information concerning the consequences of the intervention and the potential alternatives so that a voluntary decision to authorize or refuse a medical procedure can be made. In bioethical contexts *competence* implies the ability to make a decision as to whether or not a therapeutic or diagnostic procedure should be undertaken.[7] The patient's decision should reflect rational considerations based on information given by the physician. The process of *disclosure* includes information on the nature of the disease, prognosis and risks and benefits of the various options. However, there seems to be a considerable lack of *understanding* by patients of the procedure of resuscitation and the prognostic implications. For example, it has been demonstrated that providing knowledge about CPR and survival rate can lead to a marked decrease in consent to resuscitation in the elderly.[39] A high percentage (41%) of ambulatory patients interviewed in a geriatric practice said they would opt for CPR if they had a cardiac arrest during an acute illness. In the case of cardiac arrest during a chronic illness (life expectancy less than 1 yr), the number of patients choosing CPR decreased considerably (11%). There was a further reduction in acceptance of resuscitation attempts after additional information was disclosed as to the probable rate of survival in both conditions: now only 22% would still opt for CPR during an acute illness, and only 5% of the elderly patients would choose to undergo CPR during a chronic disease. These results emphasize the essential need for prognostic information for the patient to make an informed decision concerning CPR.[39]

Patient's autonomy in resuscitation

Voluntariness means "being free to act", a vital precondition for autonomous *authorization* of a diagnostic or therapeutic intervention.[7] However, within seconds after cardiac arrest the patient loses consciousness, and thus his decision-making capacity. He is incapable of communicating his treatment preferences, or his right to accept or reject treatment. Thus the decision to perform CPR in sudden cardiac arrest is usually made without the patient's involvement. Consent to administer CPR is presumed. Physicians (and all others involved) have an obligation to serve as the patient's advocate by attempting to avoid undue harm. Such behaviour might be judged a "paternalistic" approach in medical practice, but we believe it should be considered primarily as an attempt to do what is assumed to be in the patient's best interests. Those who want to make an independent decision as to whether or not resuscitation attempts should be started must express their wishes in advance or through a surrogate.

Do-not-resuscitate orders

The patient's wish not to be resuscitated has been recognized as a potential criterion for withholding CPR.[2] Do-not-resuscitate (DNR) orders written by patients or their physicians have been established to provide a mechanism for withholding specific resuscitative therapies in the event of cardiac arrest. DNR orders mean that no measures are undertaken to restore spontaneous cardiac rhythm and respiration.[32]

Patients may write DNR orders to express their preferences in advance, at a time when they are capable of making informed decisions. These decisions are often made with regard to quality of life statements. The patient's perception of whether or not it is worthwhile to survive is based on his individual value judgements which may be influenced by religious views. Patients having lived nearly their full lifespan, living entirely dependent on others, or those with a severe underlying disease and a poor prognosis may choose to refuse life-prolonging treatment.[41] Others do not want to undergo the risk of a "nearly successful" resuscitation, with long-term intensive care treatment and without restoration of their previous health. Nevertheless, being chronically ill does not inevitably imply that the patient may refuse CPR.[41] It has been reported that even those elderly people who are severely ill or disabled opt for CPR.[17] An individual patient's expectation of CPR might not be *restitutio ad integrum*, but merely to extend his lifespan to allow participation in a forthcoming family event. Therefore physicians should assess carefully the factors which influence the patient's decision. The risk of provoking anxiety by discussing the appropriateness of resuscitation seems to be negligible.[37]

Physicians' attitudes

Respect for patient autonomy may be irrelevant when CPR has no potential benefit.[12] While patients may write a DNR order, physicians may also make a unilateral decision to withhold resuscitative attempts in a patient near death who is unable to communicate his preferences. In the patient suffering from a terminal disease, the physician's normal commitment to preserving life is not in accord with the patient's interests, if futile suffering is to be avoided. Restoring the circulation only prolongs the process of dying. If, because of the underlying disease, the patient is incapable of understanding the nature of a DNR decision and did not express preferences in advance, the options should, if appropriate, be discussed with the patient's relatives. Although the right of proxies to withhold or terminate life-sustaining treatment is not generally accepted, in the incompetent patient the physician often has to rely on the views of family members regarding the patient's potential wishes. In addition, family members may play an important role in the care of terminally ill patients, in particular if the patient is going to die at home. Relatives should be informed about the expected process of dying, possible events and their own reactions and behaviour. Patients and their relatives should be assured that any care necessary to relieve suffering will be given or continued, as withholding CPR does not mean withholding all medical treatment.[6]

In clinical practice the question arises to what extent patient preference is taken into account. Some resuscitation attempts may be performed on cardiac arrest patients who have a terminal disease and do not want the procedure. In a retrospective review, Dull and colleagues attempted to determine the percentage of resuscitation attempts which were unwanted or were undertaken in pre-hospital patients suffering conditions associated with poor survival rates.[22] Unwanted resuscitation was assumed if there was a living will, other advance directives or corresponding statements by family members or by the patient's private physician. One-third of all resuscitative attempts occurred in chronically ill patients (25%) or patients who did not want CPR (7%). The hospital discharge rate in both groups was lower than the discharge rate (16%) for cardiac arrest patients overall: 8% of patients suffering from chronic diseases and 2% who did not want to be resuscitated survived to hospital discharge.[22] These findings demonstrate the difficulties in elucidating pre-arrest conditions with poor prognoses and the limitations in honouring living wills and DNR orders in the field. Sometimes family members may panic in the face of death and call the emergency medical service, leading to unwanted resuscitation attempts.

On the other hand, the absence of a DNR order does not necessarily mean that any patient suffering from cardiac arrest receives full resuscitative efforts. The duration and intensity of advanced cardiac life support may vary depending on the physician's perception of the likelihood of benefit to the individual patient.[26] One factor associated with short resuscitative attempts in hospitalized patients was age more than 75 yr.[26] This finding and the results of a recently published survey of emergency physicians[38] support the hypothesis that age plays an important role in the decision to terminate unsuccessful CPR, although it is widely accepted that not age, but other factors such as co-morbidity and pre-arrest functional status are more important determinants of outcome.[30 48 49 51]

Clemency and Thompson surveyed anaesthetists to determine their opinions regarding DNR orders in the perioperative period.[18] Almost two-thirds of 190 responding anaesthetists assumed DNR-suspension and only 50% discussed this assumption with the patient.[18] If a patient with a DNR order suffers intraoperative arrest because of the underlying disease, 34% of anaesthetists interviewed said they would resuscitate; 68% would perform CPR if the patient had an iatrogenic-induced arrest during surgery.[16] The withholding and withdrawing of life support by critical care physicians had been analysed to determine current practice in adult intensive care medicine.[4] One-third of physicians were reported to have refused patients' or surrogates' wishes to discontinue treatment. Many physicians also reported the unilateral decision to withhold (83%) or withdraw (82%) life-sustaining treatment which they had judged to be futile, some of these decisions being made without the patient's knowledge and consent, and some despite their objections.[4] Often patients are not involved in discussions about their DNR status, or physicians write DNR orders at a time when the majority of patients are considered incompetent.[10] Even among seriously ill hospitalized patients, only a minority (29%) said they had discussed their CPR preferences with their physician.[41]

JUSTICE

This principle affects priorities in the allocation of health-care resources. Justice may be defined as giving to each person that which is due, and which can be claimed legitimately.[7]

CPR should be allocated throughout the community and within the hospital at a comparable level. It is a matter of justice to ensure some degree of equitable distribution of medical resources to all citizens.[2] Performing CPR which is inappropriate or futile may delay or prevent emergency treatment in other patients with a better chance of survival. This conflict is not restricted to CPR efforts or to the use of expensive and scarce resources, such as intensive care units and helicopters. In times when the demands on the health care system are competing heavily because of cutbacks in available public funds, it is increasingly important to provide fairness by common agreement.

Every citizen has the right to receive CPR. However, differences in survival of pre-hospital cardiac arrest patients related to race and socio-economic status have been identified.[9 29] In Chicago, Blacks were significantly less likely to undergo initially successful resuscitation, to be admitted to hospital or to survive until the time of discharge.[9] In Seattle, a higher socio-economic status was associated with a higher rate of survival.[29] Possible explanations include better access to health care and better state of general health. Witnessed cardiac arrests and bystander CPR were less frequent in Blacks,[9] whereas there were no differences in emergency service system response times and proportion of cases receiving advanced cardiac life support.[9 20] Interviews with emergency service system personnel in Oslo demonstrated that the social status of the patient did not influence the decision of whether or not to start CPR.[40]

Taking into account the serious shortage of organs suitable for transplantation, the use of expensive medical emergency resources in pre-hospital trauma management might be justified if it provided a source of organs. Young trauma victims with isolated, mortal head injury might be excellent candidates for organ donation if their vital functions can be maintained long enough to undergo organ evaluation.[19] The appropriateness of initiating or continuing life-sustaining therapies solely for the aim of organ procurement has to be questioned. The decision to resuscitate should be based primarily on each individual's chance to survive, taking the aspects of beneficence and nonmaleficence into consideration. Therefore, the aspect of organ procurement in resuscitation is an area of considerable sensitivity requiring further discussion.[2]

Conclusions

The question of the ranking between the different ethical principles is still a matter of discussion. Autonomy has been emphasized as the primary principle from which all others derive.[24] However, respect for autonomy is not the only principle and should not be overvalued if it conflicts with other aspects. In the clinical situation of cardiac arrest, the weight of respect for autonomy may be minimal while the weight of nonmaleficence and beneficence may be maximal.[7]

Physicians have an obligation to consider the therapeutic efficacy of CPR. The optimal solution would be to start resuscitation only in those patients with the potential for long-term survival (beneficence), but this can rarely be determined at an early stage.[14] In otherwise healthy individuals the standard of care remains prompt initiation of CPR. The time frame in cardiac arrest requires medical decision-making within seconds. Failure to administer prompt CPR would result in the patient's death.

Chronic or terminally ill patients should be encouraged to determine in advance whether resuscitative efforts should be initiated in the case of cardiac arrest. In these patients cardiac arrest is not a sudden event, but the end of the process of dying and therefore might be anticipated. Patients' preferences have to be assessed carefully in a compassionate way. Some patients may feel uncomfortable making life-or-death decisions, while others want to participate in the decision-making process. The in-hospital use of DNR orders seems to be increasingly common in several countries, whereas its acceptance in the pre-hospital setting is still a matter of debate.[1] Medical guidelines, ethical policies and legal conditions have to be developed to allow emergency service system personnel to respect the patient's autonomy in the field by honouring advance directives, without the fear of legal action. There is a clear need to discuss these issues in a public forum. We do not feel that it should be mandatory for every citizen to write advance directives, but public information and education should increase the number of people doing so voluntarily.

We feel that, in some instances, to save the patient's life might not be the *final* goal. Decisions taking into account the potential futility of treatment should consider the patient's perception of quality of life by respecting his individual hierarchy of values. To survive without restoration of pre-arrest health status may be of only limited benefit to the patient with serious advanced disease. Survival with physical or mental impairment may be strenuous. Sometimes resuscitative efforts save only to prolong the dying process, whereas sudden death from cardiac arrest could seem like a release.

If there is any doubt about the appropriateness of withholding resuscitative attempts, CPR should be initiated. Life-sustaining therapies can be withdrawn at a later time when proper medical, legal and ethical considerations have been addressed more thoroughly.[1] Training programmes have to be integrated into academic education to enable physicians to analyse and deal with ethical conflicts. The physician's moral decision should be based on the knowledge of the relevant ethical principles, remembering what is expressed in the Hippocratic oath: "I will use treatment to help the sick according to my ability and judgement (beneficence), but I will never use it to injure or wrong them (nonmalevolence)".[7]

CORRESPONDENCE

Oxygenation criteria—a plea for more information

Sir,—We were interested to read the editorial by Peek and Firmin[1] arguing for the greater use of extracorporeal membrane oxygenation (ECMO) in the management of severe acute lung injury. Their results in Leicester seem impressive (although apparently unpublished elsewhere) and the authors issue a challenge to other units to match their 34% hospital survival rate in a similar group of patients. Unfortunately, however, they do not give enough information to allow this.

Values are given for the mean Murray score[2] and Pa_{O_2}/FI_{O_2} ratio in their group of 50, but more is needed if this category of patients is to be defined accurately and reproducibly. While a mean Pa_{O_2}/FI_{O_2} ratio of 8.7 provides an approximate indication of the problems with oxygen transfer in these patients, the picture is incomplete First, it would be helpful to know how long the problems persisted at this level before extracorporeal support was started; was it one or more hours or was the mean calculated from the single worst value for each patient and so based in each case on a single blood-gas result? Second, apart from the Murray score which includes positive end-expiratory pressure (PEEP) as one component, we are given little clue as to mean airway pressure at this time, despite the fact that this is accepted as being a major determinant of arterial oxygenation.[3]

As long ago as the 1970s the importance of at least some reference to airway pressure was recognized and the American ECMO study entry criteria reflected this by referring to specific levels of PEEP together with defined requirements for FI_{O_2} and Pa_{O_2}.[4] At the time, this was reasonable in that PEEP was the only commonly used means of increasing mean airway pressure. It is, of course, still used extensively and is one of the components of the Murray score. However, today, particularly in the most severe forms of acute lung injury, the extensive use of inverse ratio ventilation to maximize mean airway pressure means that its relationship to the level of PEEP is less predictable. It would be helpful, therefore, if future descriptions of severity of lung injury in patients undergoing ventilation could include data on the mean airway pressure being used.

Extracorporeal membrane oxygenation in severe acute respiratory failure. *Journal of the American Medical Association* 1979; 242: 2193–2196.

Sir,—We thank Drs Nielsen and Grice for their interest in our editorial. We agree fully with their comments that the Murray score and Pa_{O_2}/FI_{O_2} ratios do not provide a full picture of the severity and duration of respiratory failure. Unfortunately, it is not possible to discuss these factors in full within the framework of an editorial. Since the publication of our editorial we have heard that the detailed report of the patients alluded to has been accepted for publication in *Chest*. Data on duration of ventilation, airway pressures, minute ventilation and many other variables will be presented therein. We invite further discussion after publication of this paper.

Lateral positioning for regional analgesia during labour

Sir,—The letter by Richardson and Wissler[1] described several cases of labouring women who had extradural test doses while in the sitting position. They were placed in the left lateral recumbent position only after development of high spinal block. The sitting position may cause problems both in the spread of drug in the subarachnoid space, as highlighted by the authors, and also in the cardiovascular consequences of regional block.

Richardson, Lee and Wissler's initial report[2] suggested that cephalad spread in these cases may have been more extensive than would have been expected if patients were in the lateral position. Hamilton and Cohen also discussed extensive cephalad spread of isobaric solution while sitting as a factor in cases of high sensory block[3] or respiratory depression[4] after intrathecal sufentanil analgesia. Various "isobaric" solutions are hypobaric both *in vitro*[5] and *in vivo*.[6]

Richardson and Wissler changed their local anaesthetic test dose from lignocaine 45 mg to bupivacaine 5 mg Bupivacaine is theoretically safer if a high block results because of its greater sensory–motor differential than lignocaine. However, the dose of bupivacaine (0.25% solution 2 ml) may not be adequate. Stacey and colleagues[7] used bupivacaine 5 mg to produce spinal analgesia in labour. Although sympathetic block was usually present 5 min after this dose, analgesia was present in only two-thirds of patients and moderate to severe motor block did not develop in one-third of women. Furthermore, the deadspace of the extradural catheter and filter, if used, may vary from 0.25 to 1 ml. Therefore, only 2.5–4.375 mg of bupivacaine may enter the spinal canal. A large number of false negative test doses are to be expected.

The answer would seem to be to use a larger dose of bupivacaine, but manage the woman in the lateral position so that the effects of baricity alter lateral rather than cephalad spread.[6]

Position also has major effects on venous return. Sitting is associated with orthostatic stress on the circulation which may be combined with inferior vena caval compression during late pregnancy.[8 9] Greene and Brull[10] stressed the importance of a slight head-down tilt during spinal anaesthesia for this reason. Maintaining labouring women sitting after administration of isobaric spinal solutions or extradural test doses may result in greater hypotension than if they were lateral; this is exacerbated if the block is subsequently unexpectedly high.

The position in which the woman is managed for the first dose and thereafter usually follows on from the position chosen for insertion of the regional block. Vincent and Chestnut[9] found no overall difference in comfort if women curled up sitting and then lateral as for regional block, but in those who expressed a preference slimmer women preferred the lateral position and larger women preferred sitting. I ask women who request regional analgesia during labour which position they think will be most comfortable for insertion of the block, the majority indicate the lateral recumbent position rather than sitting. This is to be expected in our population with a low mean body mass index.[9] As far as the operator is concerned, anaesthetists who prefer to perform extradurals with the woman sitting find it harder if she is positioned laterally. The converse is not the case: if they prefer the lateral position for insertion, it is equally easy to place extradural catheters with the woman in either position.[11] Trainees should be encouraged to use the lateral position for regional block during labour, because there are occasions when this may be indicated clinically.[12]

I believe the lateral position to be optimal for administration of spinal or potentially spinal drugs, not only for the woman's comfort, but also in terms of safety. If the sitting position is deemed necessary for insertion of the block, consideration should be given to repositioning the woman into the lateral position, immediately (for intended spinal anaesthesia using isobaric solutions) or before an extradural test dose.

Sir,—We appreciate Dr Kinsella's interest in our letter. He and other authors continue to refer to non-glucose-containing anaesthetics as "isobaric solutions". We have shown that glucose-free local anaesthetics, opioids and combinations, commonly used for intrathecal administration for analgesia in labour, are hypobaric relative to the cerebrospinal fluid.[1,2] We and others have observed positional effects on the extent of block in labouring parturients which are likely to be attributable to the hypobaricity of the intrathecal injectate.[3] Although the clinical significance of hypobaricity and patient positioning as factors contributing to the extent of block remains to be fully elucidated, these solutions should no longer be referred to as isobaric.[1]

In 1981, Moore and Batra described the simultaneous injection of lignocaine and adrenaline as a test to detect occult i.v. or intrathecal placement of the extradural catheter.[4] Although they reported only on the predictive value of the i.v. component (adrenaline) in non-pregnant patients, their test dose rapidly gained acceptance for use in parturients. For years, investigators have focused on the safety, sensitivity and specificity of the i.v. component (adrenaline). Although the intrathecal component has received attention recently, we are unaware of any study that has evaluated the safety or predictive value of the intrathecal component of an extradural test dose in labouring parturients. Despite this, there is much published opinion on the correct test for intrathecal catheter detection in this population. The cases reported by us and others[5–7] serve to suggest that the local anaesthetic component (lignocaine 45 mg) described by Moore and Batra (and still used by many today) is excessive in the labouring parturient. This is not surprising, as relatively minuscule doses of intrathecal bupivacaine (with or without opioid) produce rapid and profound analgesia in labour. The current use of dilute anaesthetic solutions for extradural analgesia in labour has effectively eliminated the risk of systemic toxicity from the initial therapeutic dose, and has rightly focused our attention on the possibility of accidental high spinal block in the parturient.

Dr Kinsella suggests that the sensitivity of a 2-ml test dose containing bupivacaine 5 mg and adrenaline 15 μg in labouring parturients may be unacceptably low. Stacey and colleagues[8] administered the same dose of hypobaric bupivacaine (5 mg in 2 ml) to labouring parturients in the left lateral position (parturients were not moved after intrathecal injection). The authors reported detectable sensory analgesic levels and "substantial pain relief" in all 30 parturients. The extent of analgesic block varied considerably, probably attributable to inadequate cephalad spread of the hypobaric solution administered in the lateral position.[3] Subsequent to publication of our letter, we have detected two intrathecal catheters using the bupivacaine–adrenaline test dose. In both cases, sensory analgesia was detected promptly and seated parturients were moved to the lateral position; neither experienced significant changes in haemodynamic state and both had immediate and complete analgesia. Sensory blocks were dense and easily demonstrated and motor block was restricted to the lower extremities. The dramatic and rapid sensory and analgesic effects observed in both cases indicate to us that false negative intrathecal tests are very unlikely; we have not observed any thus far. However, in the event of a false negative test, the ensuing fractionated administration of the therapeutic dose (typically including fentanyl and a total of bupivacaine 12.5–20 mg) with the parturient positioned laterally further safeguards against the potentially catastrophic complications of high spinal block. We shall continue to use this testing method until further data become available.

Some investigators recommend extradural test doses containing amounts of bupivacaine known to rapidly produce high levels of dense sensory and motor anaesthesia adequate for Caesarean section.[9] We have never advocated such practice as there have been no studies on the safety of intrathecal injection of these large bupivacaine doses in labouring parturients who receive smaller amounts of i.v. prehydration. Although large intrathecal doses of bupivacaine produce dramatic effects, we believe that careful questioning and examination by the experienced anaesthetist at the time of administration of the test dose are preferable to induction of extensive and profound subarachnoid block in the labour room.

The clinical significance of positional effects on the haemodynamic state of the parturient has not been determined, and may or may not be influenced by feto–maternal health Today, it is not uncommon for healthy parturients to assume the upright position after administration of intrathecal and extradural local anaesthetics. We do not routinely dictate patient position during extradural catheter placement, but rather allow the parturient to chose the position most comfortable to her. We agree with Dr Kinsella's comments on development of skill in performing regional anaesthesia in parturients positioned laterally. Such practice undoubtedly contributes to success in performing spinal anaesthesia for many emergency Caesarean sections which would otherwise be performed under general anaesthesia.

Interactions between mivacurium and prilocaine

Sir,—In their study of mivacurium supplementation of i.v. regional anaesthesia with prilocaine in volunteers, Torrance, Lewer and Galletly noted that the duration of action of mivacurium was prolonged significantly beyond that which was expected, and that the incidence of systemic effects from prilocaine after tourniquet release was much increased when mivacurium was also given.[1] The authors did not provide any explanation for these phenomena and I would offer the following.

In common with all amide local anaesthetics (hence dibucaine number) prilocaine is a potent inhibitor of plasma cholinesterase.[2] Thus metabolism of mivacurium by plasma cholinesterase would be inhibited and its effects exaggerated. Until now, I have always thought of this as a theoretical, rather than a clinically relevant, interaction, but it is clearly important for mivacurium.

I wonder if the increased incidence of systemic effects of prilocaine after tourniquet release can be explained by some of the observations made during the study. Urticarial wheals were noted in two of the five volunteers who received mivacurium and prilocaine, and the authors concluded that the former produced an increase in vascular permeability. I would suggest that this might allow prilocaine to diffuse more rapidly into the blood from the tissues of the forearm after tourniquet release and so produce a more rapid increase in plasma concentration to a higher peak. Evidence of systemic effects would thus be more likely.

2. Zsigmond EK, Kothary SP, Flynn KB. In vitro inhibitory effect of amide-type local analgesics on normal and atypical human plasma cholinesterases. *Regional Anesthesia* 1978; 3/4: 7–9.

Sir,—We thank Dr Wildsmith for his comments. While inhibition of pseudocholinesterase by prilocaine in the isolated limb would explain the absence of mivacurium catabolism when the cuff was inflated, I would have expected two things to occur on cuff deflation: first, an influx of uninhibited pseudocholinesterase leading to mivacurium catabolism rather than prolonged weakness; and second, the small dose of mivacurium that was administered would redistribute throughout the body and become so diluted that its effect would be minimal. In this case the weakness remained localized to the arm and did not become generalized. I suggest therefore that the prolonged block produced by mivacurium in the isolated limb must be caused, at least in part, by the kinetics of mivacurium binding within the biophase of the limb.

The effect of altered vascular permeability on absorption of prilocaine might be investigated by measuring blood concentrations of prilocaine after prilocaine infiltration within the isolated limb, with and without a dose of i.v. mivacurium. We intend to investigate these interactions further.

Effects of volume on spinal anaesthesia with 0.25% hyperbaric bupivacaine

Sir,—Chung and colleagues[1] reported their clinical results on spinal anaesthesia with hyperbaric bupivacaine. Three groups (1, 2 and 3) of term parturients received 0.25% bupivacaine 3.2–3.6 ml (8–9 mg), 3.6–4.0 ml (9–10 mg) and 4.0–4.4 ml (10–11 mg) in 5% glucose, respectively. They found that cephalad spread of sensory analgesia was increased significantly with an increase in volume, and the onset time of sensory analgesia to T6 was significantly faster in group 3 than in group 1. The mean maximal level of analgesia in group 3 (T2–3) was significantly higher than that in groups 1 and 2 (T4–5 in each). They concluded that a large volume in itself may influence the spread of local anaesthetic in cerebrospinal fluid (CSF) and final block, especially in the narrow subarachnoid space of term parturients. Our clinical investigations with isobaric and hyperbaric amylocaine in parturients (King HK, Wood L, Khan AK. Spinal anaesthesia for Caesarean section. isobaric *vs* hyperbaric solution, unpublished data) and isobaric amylocaine in non-pregnant patients[2] produced similar results indicating that the volume of local anaesthetic is the most immediate significant factor affecting the extent of spread because of simple "bulk displacement" or area of contact; that is the greater the volume, the more extensive is the spread.

An anaesthetic solution administered into the subarachnoid space is diluted by CSF and absorbed by the neural tissues during spread. A hyperbaric solution has a density greater than that of CSF. When the patient is in the horizontal supine position, the subarachnoid space is inclined downward from the lumbar lordosis, towards the low-lying parts, in both caudad and cephalad directions, and the hyperbaric solution reaches the lowest points in both directions unless its baricity is decreased to CSF during the process. Additionally, we may surmise that when the drug concentration has reached its minimal pharmacologically active concentration, no clinical analgesia can be detected even if the solution spreads further. Moreover, sacral pooling of hyperbaric solution reduces the mass (effective dose, amount undetectable) of local anaesthetic that spreads cephalad and subsequently affects the results observed.

Chung and colleagues[1] used the same 0.25% hyperbaric bupivacaine solution. As increasing the volume of local anaesthetic solution implies an increase in drug dose, the results obtained may also have been affected by the dose of drug.[3 4] With multiple factors such as drug volume, dose and baricity/position effects, the claim that the results obtained in this study were caused by drug volume alone is not justifiable.

Converting pH and H^+

Sir,—Further to the letter by Burden and McQuillan[1] on converting pH and H^+, I was taught the following trick nearly 30 yr ago by Professor Roy Simpson. Between pH 8.0 at 10 nmol $litre^{-1}$ hydrogen ion concentration and pH 7.0 at 100 nmol $litre^{-1}$, simply double or halve the hydrogen ion concentration for each 0.3 pH unit (table 1).

Table 1 Method of converting pH to H^+

pH	8.0	7.9	7.7	7.6	7.4	7.3	7.1	7.0
H^+	10	12·5	20	25	40	50	80	100

This method is easy to remember and a good demonstration of a logarithmic progression for juniors to learn.

"Renal" dopamine

Sir,—We read with interest the recent study[1] and editorial[2] regarding the use of low-dose, "renal" dopamine. The study by Girbes and colleagues appeared to provide further evidence that the effects in question result from an increase in cardiac output. The editorial by McCrory and Cunningham concluded that attention to dobutamine should be considered. There are two important points which we feel have been overlooked.

First, in a study by Zaritsky and colleagues[3] on dopamine pharmacokinetics in critically ill infants and children, the authors concluded "substantial interindividual variation was observed in steady state dopamine clearance, . . . plasma dopamine could not be predicted accurately from the infusion rate". Different texts quote varying dose ranges for the renal–inotropic–vasoconstrictor effects of dopamine and this arouses suspicion. This study showed that with such pharmacodynamic variation it is impossible to predict the effects produced by a fixed rate infusion of dopamine in a critically ill patient.

Second, a study by Duke, Briedis and Weaver[4] compared low-dose dopamine with low-dose dobutamine. They studied 18 intensive care patients, each receiving, in random order, dopamine, dobutamine and placebo. They found a higher incidence of side effects with dopamine (tachycardia, hypertension, hypovolaemia and worsened Po_2/Fi_{O_2} ratio). The study found that while dopamine produced significant diuresis with no change in creatinine clearance, dobutamine produced significant improvement in creatinine clearance without diuresis.

Taken together these studies undermine the cosy rationale of "renal" dopamine. The pharmacodynamic case to justify infusion rate *vs* effects in intensive care is untenable. Dopamine appears to act as a diuretic but with side effects including those related to catecholamines. Dobutamine may not produce the gratifying increase in urine output but appears to produce improvement in renal function with less side effects. An increasing number of intensive care units are abandoning the uncritical use of dopamine and adopting a more scientific rationale for haemodynamic management. The recent study and editorial add to this evidence.

A. Inglis
Intensive Therapy Unit
G. Hilditch
Department of Anaesthesia
Western Infirmary
Glasgow

1. Girbes ARJ, Lieverse AG, Smit AJ, van Veldhuisen DJ, Zwaveling JH, Meijer S, Reitsma WD. Lack of specific renal haemodynamic effects of different doses of dopamine after infrarenal aortic surgery. *British Journal of Anaesthesia* 1996; 77: 753–757.
2. McCrory C, Cunningham AJ Low-dose dopamine: will there ever be a scientific rationale? *British Journal of Anaesthesia* 1997; 78: 350–351.
3. Zaritsky A, Lotze A, Stull R, Goldstein DS. Steady-state dopamine clearance in critically ill infants and children. *Critical Care Medicine* 1988; 16: 217–220.
4. Duke GJ, Briedis JH, Weaver RA. Renal support in critically ill patients: Low-dose dopamine or low-dose dobutamine? *Critical Care Medicine* 1994, 22: 1919–1925.

Sir,—Inglis and Hilditch refer to two important topics. First, they state that it is impossible to predict the effect of a given dose of dopamine because of the pharmacodynamic variation of dopamine. In our recently published study,[1] we also measured plasma dopamine concentrations by HPLC, as described in the article (table 1). In another yet unpublished study in seven healthy volunteers, dopamine at a rate of 4 $\mu g\ kg^{-1}\ min^{-1}$ was given during simultaneous infusion with different doses of noradrenaline while measuring systemic and renal haemodynamics. It is clear from the data that interindividual differences are substantial, which underscores the pharmacodynamic variation.

Table 1 Plasma concentrations of dopamine in patients (n=7) after infrarenal aortic surgery and in healthy volunteers (n=7) during simultaneous infusion with different doses of noradrenaline. Each time indicates 1 h of infusion. Plasma dopamine concentrations are represented as medians (interquartile range). nd=not detectable

Time (h)	Dopamine dose ($\mu g\ kg^{-1}\ min^{-1}$)	Plasma dopamine (nmol litre^{-1})
Patients		
Baseline	0	5.0 (2.7–11.3)
t1	2	297 (75–337)
t2	4	410 (110–683)
t3	8	413 (268–589)
t4	0	11·9 (9–108)
Healthy volunteers		
Baseline	0	nd
t1	4	463 (263–669)
t2	4	710 (327–1104)
t3	4	664 (345–934)
t4	0	nd

However, another important feature of dopamine should be mentioned, that is the different sensitivity and effects in different patient groups (and individuals). Our group and others have reported on these different effects of dopamine (agonists) with respect to renal haemodynamic state and plasma noradrenaline concentrations. In patients with a glomerular filtration rate (GFR) <50 ml 1.73 m^{-2}, dopamine was unable to increase GFR or renal blood flow.[2] The effect on renal haemodynamics in patients with congestive heart failure is, in contrast, more pronounced than in healthy volunteers.[3] The same is true for the DA_2 receptor stimulation related suppression of noradrenaline release from the presynaptic terminal of sympathetic nerves.[4] Furthermore, it has been shown, or at least been shown highly likely, that the response to DA_1 receptor stimulation is genetically determined.[5 6]

With respect to the second remark by Inglis and Hilditch, we agree that it becomes more and more clear that the renal haemodynamic effects result mainly from the systemic haemodynamic effects of dopamine. We disagree however with their conclusion that dobutamine produces less side effects, based on a single study. Furthermore, the cited study by Duke, Briedis and Weaver[7] mentioned tachycardia and hypertension in four and three of 18 patients as a side effect of dobutamine, respectively. An important flaw of this study, in our view, is the introduction of carry-over effects of dobutamine because of the sequential design. We agree however, that the uncritical use of dopamine (as a "renal" dose) should be abandoned, but the same holds true for dobutamine Low-dose dopamine is probably a useful drug in the initial treatment of (severe) congestive heart failure and will remain useful in the initial treatment of hypotensive patients, in whom the diagnosis is not yet established.[8]

BOOK REVIEWS

Manual of Drug Interactions for Anesthesiology, 3rd Edn. R. A. MUELLER AND D. B. A. LUNDBERG Published by Churchill Livingstone, Edinburgh. Pp. 503; indexed; illustrated Price £30.00.

This is a manual aimed at the practising anaesthetist which, despite its title, is more concerned with side effects than true drug interactions. The authors have concentrated on reactions between anaesthetic drugs and concomitant medication rather than those between non-anaesthetic drugs.

The book is in three sections: an index, a general chapter entitled the "Philosophy and theory" of drug interactions, and a catalogue of side effects and drug interactions. The index is comprehensive and an effort has been made to include British and North American drug names. This is not always consistent, for example lignocaine but not pethidine, adrenaline but not noradrenaline. Anaesthetic drugs are not included in the index but are referred to under the drug with which they are said to interact. The general chapter comprises approximately 5% of the book and documents the pharmacokinetic and pharmacodynamic factors which may be responsible for drug interactions. Although this is probably the best part of the book, and the only part which is referenced, it offers no particular insights beyond those obtainable in any number of pharmacological textbooks. Finally, groups of drugs are catalogued according to their principal clinical usage—antihistamines, anti-infectives, antimitotics through to hormone agonists/antagonists and miscellaneous.

One of the difficulties of a manual such as this is defining what is meant by a drug interaction. The authors have not highlighted those interactions which might be considered dangerous, and equal weight is given to reactions which most clinicians would regard as trivial, for example halogenated hydrocarbons and vitamin E, glipizide, tolbutamide, imipramine and phenytoin. Unfortunately, some of the information is incorrect or misleading. There is no evidence that, in normal doses, diazepam reduces arterial pressure except in the presence of hypovolaemia. Meperidine (pethidine) (p. 333) does not increase smooth muscle tone and induce spasm of the sphincter of Oddi—quite the opposite!

Some of the statements veer on the egregious. For example, under the heading of "lidocaine" (p. 250) the authors state that, "as in all patients requiring antiarrhythmic therapy, the use of volatile halogenated hydrocarbon anaesthetics is probably contraindicated". Does this include the ethers or just halothane, and where is the evidence for such a claim? Similarly, they advise against nitrous oxide for "long cases" in patients receiving paracetamol unless the granulocyte count is normal. They also warn of hypothermia in these patients! Has the surgeon nothing to do with this? Under indomethacin (p. 317) the authors advise against general anaesthesia with halogenated hydrocarbon anaesthetics and nitrous oxide.

Surprisingly, there is no mention of interactions between sevoflurane (and other ethers) and soda-lime or Baralyme. The very dangerous interaction (torsades de pointes) between cisapride and fluconazole (or other antifungal drugs) is also ignored despite the potential for co-administration in the intensive care unit.

There is little useful information on drug interactions in this manual that cannot be found in a more authoritative form in appendix 1 of the much-maligned, freely distributed *British National Formulary*.

Critical Care, 3rd Edn. J M. CIVETTA, R. W. TAYLOR AND R. R. KIRBY (editors). Published by Lippincott-Raven, Philadelphia. Pp. 2363; indexed; illustrated.

This is a tome: a 2300-page, 3-inch thick, 9lb 4oz book, with 206 contributors who have marshalled their thoughts into 156 chapters. With a book such as this, there was little chance to do justice to it by reading it from cover to cover, so I asked myself the purpose of such a book, in the age of the CD and the laptop computer. Quite simply, despite all our electronic aids, we shall not be able to do without mammoth textbooks for years to come. It is the means by which we obtain information at 03:00 (or when the SHO rings you at home). We require a large reasonably up-to-date text in which we can find information easily and (when the need arises) obtain in-depth information in one source. This "source" has made it to the third edition. Our laptops still have someway to go in replacing paper, despite their modems and search facilities.

I started with the index: it is comprehensive, covering 80 pages of three columns of 10-pt print (equivalent to approximately 5% of the book). I looked up treatment on my most recent ICU admission: lithium poisoning. Although there was much on toxicology and clinical manifestations there was little detail on treatment: the ICU physician will usually be presented with the diagnosis. My initial (non-statistically valid) enthusiasm for the text was under threat.

I looked over the chapter headings. The book is divided into 17 sections, each with a variable number of chapters. Sections cover the usually expected areas, for example pathophysiology, monitoring, organ failure, etc, but also the unusual decision making, rheumatic disorders. Although I did not read the preface first (!) I noted that there was a clear editorial decision to have a standard opening "Immediate concerns", with a subheading "Stress points", suggesting that anything of importance (I would have presumed "clinical importance") would be mentioned in this opening. This is not quite what happens in every chapter, and discloses the American origin of the text. Thus for the chapter entitled "Vascular cannulation", an early "immediate concern" is the discussion between the operator and patient on the benefits, risks and alternatives of the chosen techniques (the medico-legal aspects?). I cannot see this happening in the UK when presented with patients on whom we most commonly use our skills (i.e emergencies) who are often unable to communicate. In the same chapter, there is discussion about the Allen (sic) test. The authors state that they do not advocate its use: when will we simply admit that it is not done and is of no benefit! Other chapters (and "immediate concerns") are good and precise, for example "phaeochromocytoma", which has a chapter of its own, and which I read in detail to see if I was doing it correctly! However, interesting though it was, does phaeochromocytoma deserve eight pages when ARDS is covered in only 16 pages? I was also particularly interested by the good chapter on respiratory muscle fatigue, but it got lost in the chapter on mechanical ventilation There is further evidence of the North American–European divide: American "BIPAP" (bilevel positive airway pressure") for non-intubated ventilatory support and (unmentioned) European "BiPAP" (biphasic positive airway pressure) for patients receiving preset pressure controlled ventilation.

Throughout my time with this book, I have looked up individual topics and generally grazed with little malice aforethought. The book is clearly American, and reflects American practice It spans much greater areas and includes topics in the UK that would not usually be included in a critical care text (e.g. hypertensive urgencies) and drugs not usually used or unavailable (e.g. nicardipine for hypertension, acetylcysteine to liquefy sputum). In the end, what I liked best about the book was the opening section on "decision making" which included such topics as "how to read a paper" in addition to ethical decision making.

What did I think of the book overall? I liked it much better than in the words of Alan Wicker "some others I could name". It is a well illustrated, well researched, comprehensive necessary evil This book, or something similar, is a required bench book in every ICU. Placing it in the hospital library is a waste of a resource. Most chapters have up-to-date (1995) references, although in one (chapter 145) the most up-to-date reference was 1985. However, this is not the curate's egg. Most of it is good.

P. G. Lawler

Pain Management for the Practising Physician. G A. IRVING AND M WALLANCE. Published by Churchill Livingstone, Edinburgh. Pp. 330; indexed, illustrated. Price £32.50.

The authors' have aimed this text at medical students, house officers and general practitioners to provide easy to follow advice on pain management for non-pain specialists. The book is divided into five sections and is preceded by an introduction which contains a useful glossary of pain terminology. Section 1 provides essentials of pain anatomy, physiology and pharmacology, although there are one or two errors, for example the sigma receptor is defined as an opioid receptor. Section 2, which comprises approximately two-thirds of the book, consists of short chapters on various pain conditions presented in alphabetical order. The emphasis is very much on treatment and this is presented in outline in the form of algorithms with supporting text. In addition, each chapter concludes with a case study, which emphasizes the multimodal approach to pain management which does not appear obvious in the algorithms. Section 3 presents a useful introduction into psychological aspects of pain management, and sections 4 and 5 cover non-pharmacological pain therapies and possible future treatments, respectively.

This book provides an easily read introduction to pain management, although the general style makes it very repetitive. The authors' personal opinions are clearly prevalent, particularly with regard to treatment algorithms. The algorithms and guidelines give the impression that, armed with this book, junior doctors should be able to tackle most chronic pain patients, but it lacks advice on history and examination of the pain patient which is relevant for those to whom the book is aimed. On the other hand, general practitioners may find this book of more practical use.

R. Atcheson

The Pulmonary Circulation: Moving From Passive to Active Control. M. R PINSKY, J.-F. DHAINAUT AND A. ARTIGAS (editors). Published by WB Saunders, London. Pp. 295; indexed; illustrated. Price £45.00.

This book contains the proceedings of an international symposium on the pulmonary circulation which took place in 1995. It consists of 19 chapters written by international experts from both sides of the Atlantic. The quality and length of the chapters are extremely variable; there are excellent reviews of endothelin and other pulmonary vasoconstrictors, leucocyte migration and mechanisms of pulmonary oedema formation. There are also several reports of original research, including work on the cardiopulmonary effect of home oxygen therapy and the combined effect of inhaled nitric oxide and pulmonary vasoconstrictors.

There is inevitably a large amount of duplication within the book. The mechanisms of action of nitric oxide, and details of the endothelin and arachadonic acid pathways appear in multiple chapters.

At a price of £45 this book might be a useful purchase for the library or department with an interest in this field, but is not a book for the general anaesthetist or intensivist's personal collection.

J. D. Young

The Pulmonary Artery Catheter in Critical Care—A Concise Handbook. C. PERRET, D. TAGAN, F. FEIHL AND J. J. MARINE. Published by Blackwell Science, Oxford. Pp. 940; indexed; illustrated. Price £55 00.

This concise book is an excellent reference manual for the use of a pulmonary artery catheter. In the preface the authors highlight the criticism that pulmonary artery catheters are used frequently with woefully inadequate expertise and this text seeks to provide a "quick and easy" source of both practical and theoretical information. It succeeds. The book is well laid out with easy access to the wealth of information within it. It is comprehensive, covering insertion techniques through measurement problems to the meaning and use of derived values: it has a large selection of case studies. The diagrams are clear, relevant and numerous.

The authors have placed pertinent references at the bottom of the relevant page which makes it very effective in its use as a reference text. There are useful lists of symbols, abbreviations and formulae and there is a short but informative section on definitions which describes both the meaning and misconceptions of commonly used terms, such as preload and afterload.

If there is a significant criticism it is that the authors appear to have a strong bias towards the positive aspects of the use of the catheter and do not address the issue of its genuine clinical value. The extensive list of indications is not balanced by a larger list of situations where the cost benefit of placing the catheter mitigates against its use.

I think this is an excellent book to have in the ICU. This book should be recommended reading for those who confidently use pulmonary artery catheters and compulsory reading for those being trained in their use.

N. Soni

Hyperthermic and Hypermetabolic Disorders. P. M. HOPKINS AND F. R. ELLIS (editors). Published by Cambridge University Press, Cambridge. Pp 286; indexed. £50.00.

It has long been a contention by some North American workers in malignant hyperthermia (MH) that the condition can be triggered by factors other than exposure to the relevant anaesthetic agents, as in the pig; for example trauma, stress and severe exercise. No such condition has yet been described convincingly in Europe This text, edited by two of the leading authorities on MH in Europe, both from the Leeds MH investigation unit, appears to have been written with the underlying assumption that such a link may exist. The book is divided into two main sections: the first covers exertional heat stroke and the second malignant hyperthermia. There are seven chapters in each section, with a third section of three chapters (one on neuroleptic malignant syndrome, one on drug overdose (tricyclics antidepressants, amphetamines, cocaine, anticholinergics, etc.) and one on endocrine (thyroid and adrenal) disease). The main thrust is exertion-induced heat injury and MH.

The exertional hyperthermia section is practical, with the first two chapters based on experience in the armed forces, principally the army. (Naval and air force personnel apparently rarely suffer from the condition.) The emphasis is on precipitating factors and clinical management, leading to discussion of the physiological testing of subjects' susceptibility to heat, the use of nuclear magnetic resonance spectroscopy to investigate muscle metabolism and ending with a review of *in vitro* muscle contracture testing for MH in heat injury victims; all of this is inconclusive other than that some individuals who become hyperthermic with exercise have a myopathy which responds in an equivocal manner to the various MH *in vitro* contracture tests.

The second seven chapters comprise an up-to-date and detailed review of MH, including details, with tracings, of the various *in vitro* tests carried out in confirming, or excluding, the diagnosis. This part should be prescribed reading for all examination candidates and for those referring patients for investigation.

I found much of the first part of this book too anecdotal, although with such a condition this is probably inevitable. I felt also that it could have benefited from an introductory chapter on thermal physiology in general to bring together all the various mechanisms and conditions discussed, and in this respect the book felt somewhat disjointed. It is however very readable and informative and I would strongly recommend it, particularly for its detailed account of the diagnostic laboratory investigations, to all those responsible for running their departmental libraries.

I. T. Campbell

Intensive Care Manual, 4th Edn. T. E. OH (editor). Published by Butterworth–Heinemann, Oxford. Pp. 1032; indexed; illustrated. Price £40.00.

The fourth edition of the successful *Intensive Care Manual* continues to bridge the gap between the weighty, comprehensive reference text and the smaller, more abridged handbook. First published in 1979, the *Intensive Care Manual* has developed into a substantial volume that could be described as either a concise textbook or a comprehensive manual. The fourth edition comprises 18 sections covering a spectrum of broad headings, for example organization aspects, acute coronary care, respiratory failure, neurological disorders, etc. Each section is made up of 4–10 chapters representing a total of 110 chapters in 1032 pages. Each chapter contains numerous references, which are either contemporary or landmark papers, and provide the reader with the option to research a subject in more detail. To produce such a huge amount of easily accessible and readable factual information the editor has drawn upon a team of 63 contributors, most of whom are dedicated intensivists. Despite this the style and format are remarkably uniform with little of the redundant, superfluous prose found in many textbooks.

It is not possible to describe all the additional material that has been incorporated into this edition but most of it represents either recent advances or topical issues in the specialty. There is a new chapter on severe soft tissue infections which contains a concise, well-referenced section on necrotizing fasciitis and a chapter on meningitis and encephalomyelitis that excludes, surprisingly, a description of herpes simplex infection. There is a larger, more inclusive, section on paediatric intensive care and coverage of haematological malignancies and immune deficiency syndrome is expanded.

Overall the *Intensive Care Manual* covers a wide range of relevant and accessible information, presented in a concise and lucid manner. It provides comprehensive practical guidance for both routine and complex diagnostic and therapeutic decisions. I would recommend this book as the primary text for every trainee in the field of intensive care and that a copy be held in every intensive care unit for the immediate use of consultants, trainees and nurses.

D. Turner

Critical Care Medicine: Perioperative Management. M. MURRAY, D. COURSIN, R. PEARL AND D. PROUGH (editors). Published by Lippincott–Raven, Philadelphia. Pp. 315; indexed; illustrated.

This book envisages a role for anaesthesiologists in the United States of America similar to the role that anaesthetists in the UK already occupy. It is aimed at the anaesthesiologist with foresight, the specialist in perioperative care who is not only a clinician but also a politician, an educator and a businessman.

Perioperative care differs from critical care, which in the USA is fragmented and rarely involves anaesthesiologists. The editors see the important components of perioperative care as: expeditious preoperative assessment, careful anaesthetic management and appropriate postoperative care with particular expertise in airway and cannulation skills, and emergency medical care. The foreword indicates how this vision of the future applies to anaesthesiology. The anaesthesiologist will become a physician outside the operating room exercising his skills in crisis management and teamwork. The statement that the *new* anaesthesiologist will have a rewarding career sounds like a recruitment drive but suggests that the old anaesthesiologist does not.

There are some good areas covered in the book. In section 1, "organization of an intensive care unit, patient assessment and general critical care", the chapter on ethics stands out. It discusses with insight the changing ethical balance from doing the best one can for an individual patient and respecting their autonomy to exercising responsibility for the health of society as a whole with access to care for all and justice as a guiding principle. This is as relevant in the UK as it is in the USA. The discussion on the appropriate use of do not resuscitate orders during operation and the need to clarify and review such orders regularly should be read by all anaesthetists.

The second and third sections cover organ specific critical care and critical care in particular clinical circumstances. Generally these chapters are well written and provide comprehensive reviews of their subjects. The chapter on endocrine emergencies is an unusual addition which provides useful information in a clear manner.

Overall the chapters have a user friendly format. Each contains a summary, key points and an "eye to the future" section on future developments. These sections provide useful, quick reference summaries of the chapter; a volume of the "key points" would make a useful handbook.

Other parts of the book deserve mention out of interest. The chapter on quality management demonstrates the convergence of American and British health systems. Quality management is driven by insurance companies in the USA but change the name to purchasers and the same principles apply in the UK. The chapter on organization of an intensive care unit details the various members of the team and what they do, but there is no mention of trainees and the important role they play. This chapter would also benefit from a discussion of teamwork principles and of the training and educational role of intensive care. Section 1 ends with several chapters on perioperative interventions and pathophysiology. This is an odd group of chapters, ranging from intubation and cannulation skills to acid–base balance. The choice seems rather haphazard but presumably reflects American practice.

The strength of anaesthesia in the UK lies in our knowledge of normal physiology and pharmacology and our understanding of how that changes in a variety of clinical circumstances Although this book has basic science content, overall it fails to apply this clinically. There are better books on critical care and better anaesthetic books.

This book makes me proud to be an anaesthetist in the UK where anaesthesia is a recognized and respected specialty. Anaesthesiology in the USA has much to learn from the UK in terms of perioperative medicine. Interestingly, there are two Irish contributors but none from the UK. It is unfortunate that our American colleagues need this book.

M. P. Shelly

Stabilisation and Transport of the Critically Ill. N. S. MORTON, M. M. POLLACK AND P. G. M. WALLACE (editors). Published by Churchill Livingstone, Edinburgh. Pp. 256; indexed; illustrated. Price £42.50.

All anaesthetists will be familiar with the difficulties in providing safe transport for critically ill patients, both within hospital and between centres. This book brings together experts in this field and reviews scientific background and research evidence providing practical advice on the transport of these patients. It includes international experience and difficulties with particular patient groups, for example children, and closes with a section on audit, research and outcome.

It is essential reading, therefore, for those interested in, or planning, a transport service but its value to a more general readership is more questionable. There is considerable variability between chapters in both quality and content. For example, the chapter on paediatric transport is 72 pages in length and includes detailed information on paediatric intensive care that goes beyond the requirements of this book, while the chapter on head injury transport is only 17 pages in length and contains little that is not covered elsewhere in the text. As the latter is one of the commoner conditions requiring transfer, more detail would be appropriate. The final chapter on research and audit hardly mentions transport and is, in effect, a brief academic introduction to these topics.

There is considerable repetition, and many details of practical aspects, which many readers will be seeking, are difficult to find as they are included in more general chapters. The section on equipment is perhaps too specific as it recommends a particular make and model of monitor which will, almost certainly, be improved or replaced in the near future. The underlying principle of safe transport—that patients should be stabilized first and accompanied by suitably experienced and equipped staff—is emphasized repeatedly and I am sure that this is correct as failure to do this may result in tragedy. However, publicity on transfer of critically ill patients usually criticizes the fact that they require transfer rather than how it is done. A more positive approach and a higher profile for transport facilities may change this and this book is certainly a step in that direction. The production quality is generally good although some of the photographs are not particularly clear. If it is intended to function as a practical manual, it needs some reorganization; perhaps soft covers would make it more durable in addition to lowering the cost to a level that could make it an essential purchase for all intensive care units and other departments who find themselves involved with the transport of the seriously ill.

ERRATA

British Journal of Anaesthesia 1997; 78: 601–605.

p. 603. There was an error in equation (3) in which superscripted numbers were printed in normal case. Therefore, equation (3) should read:

$S = 3.207W^{0.7285-0.0188\log W}H^{0.3}$

British Journal of Anaesthesia 1997; 78: 618–625.

p. 623. There was an error in figure 6. In part D of the figure, the rectangle labelled "VE–VD" extends to the height of the dotted line, instead of stopping level with the top of the rectangle in part C. The corrected version of figure 6 is printed below.

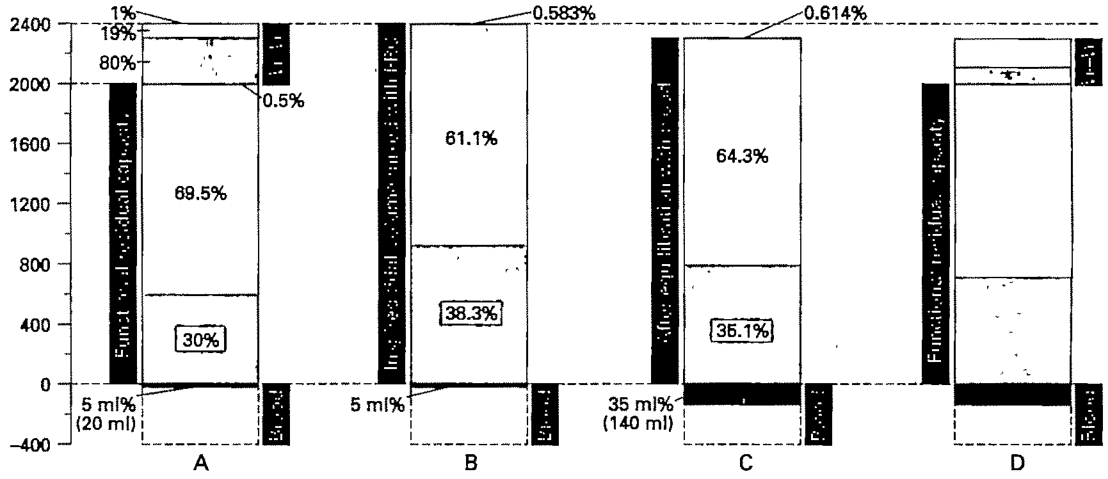

Figure 6 Constant inflow case with FRC and recirculation of anaesthetic. Single respiratory cycle during washin of nitrous oxide. An inspired mixture of 1% second gas (black), 19% oxygen (white) and 80% nitrous oxide (light shading) is used with a non-rebreathing system. The *Y*-axis shows the volume of gas or blood (ml). A: From top down, 400 ml of inspired gas mixture ($V_I - V_D$); FRC 2 litre comprising 0.5% of the second gas, 69.5% oxygen and 30% nitrous oxide; 400 ml of blood for equilibration containing 20 ml of recirculated nitrous oxide (black areas). B: After complete mixing of inspired gas with FRC. C: After equilibration of gas with 400 ml of blood ($\lambda = 1$ for nitrous oxide and 0 for oxygen and the second gas). Dissolved nitrous oxide is shown as black. D: From top down, expired alveolar tidal volume ($V_E - V_D$) = 280 ml, FRC (still 2 litre) and blood, after equilibration.

We apologize to the authors for these errors which arose during the editorial process.

"I would have everie man write what he knowes and no more."—MONTAIGNE

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 79, No. 3 SEPTEMBER 1997

EDITORIAL I

So just who was James "Young" Simpson?

November 4, 1997, sees the last of the major sesquicentenary anniversaries in our specialty—the discovery of the anaesthetic effects of chloroform. The event is being marked a little early with a meeting this month in Edinburgh, celebrating not so much the discovery of chloroform, but the whole contribution to medicine of the discoverer, James Young Simpson. Who was this man, who unlike many other early pioneers of anaesthesia was already a major medical figure at the time of his involvement? He was Professor of Midwifery at Edinburgh University, was well regarded as a lecturer, had an extensive clinical practice and had just been appointed physician to Queen Victoria. This was a member of the establishment yet he challenged the perspective of the medical world by enthusiastically embracing and advocating the use of anaesthesia, sometimes against considerable opposition.

James Simpson was born to poor parents, his father being a baker in Bathgate near Edinburgh.[1] Because he had shown aptitude at school his father and elder brothers scraped together enough money for him to attend Edinburgh University, which he entered at the age of 14 to study the arts. However, after 1 yr he transferred to the medical course and graduated 1 month before his 19th birthday, working initially as a doctor's assistant. During this time he prepared and submitted an MD thesis entitled *Death by Inflammation* which brought him to the attention of the Professor of Pathology in Edinburgh, John Thomson, who offered him employment and soon suggested obstetrics as a good career for an ambitious man. Simpson threw himself into its study and within 3 yr he was recognized as the producer of both quality research and inspiring lectures.

In November 1839, at the age of 28 yr, and at sometime having acquired the sobriquet "Young", he applied for the vacant Chair of Midwifery in Edinburgh, an appointment determined by the Lord Provost, magistrates and town council. Simpson spent £500, an extraordinary amount of money then (he was paid only £50 per annum 6 yr previously) on promoting himself and pressurizing the members of the council to vote for him. One of the criticisms raised against him was his bachelor status, a problem which he quickly overcame by proposing to a relative, Jessie Grindlay, whom he married in Liverpool on December 26, 1839. They promptly returned to Edinburgh where Simpson continued canvassing and the new Mrs Simpson was put to work cataloguing and preparing a portfolio of teaching material, possession of which was a prerequisite for the post. Their efforts were successful and the Chair was won on February 4, 1840, by one vote.[1]

During the next 7 yr he was formidably busy with both clinical and university activities. He was recognized as a leading obstetrician and the family home was always full of visiting doctors and private patients, some travelling from far afield. Despite, or perhaps because of, his enormous workload, Simpson was an obstetric innovator, devising an "air tractor" (a suction device to extract babies[2]), encouraging the use of the speculum in diagnosis and advocating hysterectomy for carcinoma. To the modern obstetrician such things are routine, but his specialty was then still in its infancy. Forceps had been available for more than 100 yr, but there was much prejudice against their use and cautery was the only treatment for uterine cancer.

Simpson also continued to be interested in general medicine and surgery, and was particularly concerned about the high rates of death after both operation and childbirth in hospital. His own statistics revealed that 1 in 53 women died postpartum in the Edinburgh Royal Maternity Hospital (the majority of puerperal fever), compared with 1 in 270 in the community.[3] This difference he attributed to cramped, dirty conditions, and he wrote of the detrimental effects of hospitalization and considered how hospitals might be better designed to minimize mortality. To confirm that hospital size and overcrowding influenced mortality, he conducted an extensive postal survey of death after traumatic and non-traumatic limb amputation in all major and cottage hospitals in the UK. Over a 10-yr period he confirmed that mortality in major hospitals was greater than in smaller units and proposed that hospitals be designed with this in mind. In addition, anything unusual attracted Simpson's attention. For example, he investigated the popular belief that a woman born with a male twin was infertile.[4] Apparently this is true of cows, something he confirmed by visiting slaughter houses and interviewing farmers, but data on childless marriages collected from two nearby towns, Bathgate and Grangemouth, showed that the fertility of women with male twins was no different to others.

In the midst of all this activity came his great claim to popular fame. Being innovative and receptive to new ideas he was immediately excited by the news from London of the successful use of ether to produce anaesthesia by Squire and Liston in December 1846. He travelled south before

Christmas to meet Liston and watch ether being used. Returning to Edinburgh he immediately used it in his own practice, initially as an anaesthetic for surgical interventions during delivery, but later for analgesia during normal labour. He publicized this use of ether, but was quickly criticized by the medical profession because of concerns about the morality and safety of providing analgesia/anaesthesia to labouring women. Simpson virtually waged war with the profession over the ethical issue, combining his own extensive knowledge of the bible with logical argument to refute the supposed religious reasons that prevented the use of anaesthesia in these patients and publishing his arguments in widely distributed pamphlets. To deal with the safety aspect Simpson used data from the Dublin Lying-in Hospital to show that mortality increased with duration of labour. He argued that anaesthesia and effective analgesia would decrease this mortality by allowing intervention and shortening labour. Of etherization he wrote: "I have no doubt whatever, that some years hence the practice will be general. Obstetricians may oppose it, but I believe our patients themselves will force the use of it upon the profession".

However, Simpson was quickly dissatisfied with ether, mainly because of its flammability and long induction time, and he sought alternatives by inhaling many chemicals with his assistants. In 1847, responding to a suggestion from David Waldie, a Liverpool chemist, chloroform was tried. Simpson, impressed with the results, reported his discovery and set about introducing chloroform into clinical practice, but he was still attacked for championing the use of anaesthesia. To challenge those who doubted its safety Simpson again turned to a large scale statistical survey, analysing both the rate and mode of death after limb amputation in patients treated with and without anaesthesia. Although the difference was small the mortality rate was slightly lower in the anaesthetized group and Simpson used these data to convince the last doubting surgeons that anaesthesia was safe.

Because of its ease of administration, chloroform soon became the most popular anaesthetic agent in the UK, but it was not long before deaths associated with its use were reported. Simpson claimed that improper administration, not a fundamental drug problem, was to blame and it was 1911 before the issue was finally resolved with the demonstration that chloroform can produce ventricular fibrillation.[5] Simpson is often criticized for his failure to concede that chloroform caused deaths and is portrayed as a man well satisfied, resting on his laurels. However, his own works reveal that this was not the case for he was always looking for better solutions. For example, he reasoned that even greater benefit would accrue if it were possible to provide anaesthesia of the surgical field alone and he was the first to use the term "local anaesthesia". He investigated the ability of compounds such as ether, benzene and chloroform to produce topical anaesthesia, and found that some "numbing" could occur with chloroform. This was inadequate for surgery, but he hoped that "some new facts and precepts may be elicited that will enable both the physician and surgeon to exhibit and apply local anaesthetics with more science, precision, and success than hitherto".

Despite all these activities Simpson's original interest in wound inflammation continued, with careful observation and research again supporting his proposals. Having seen many patients with bullet wounds, but no evidence of inflammation, he concluded that surgical wound inflammation was caused by the suture material and he proposed that metal thread should be used instead. To confirm this he carried out animal experiments[6] and later reported the successful use of platinum wire to achieve primary healing in patients. He also suggested that metal pins (removed a day later) should be applied through the skin to compress bleeding vessels.[7] This technique, called acupressure, resulted in less wound breakdown and late haemorrhage, but it required meticulous care and most surgeons quickly abandoned its use, although those who persevered achieved very good results.

As a result of his work, Simpson achieved many honours, including the Presidency of the Royal College of Physicians of Edinburgh and culminating in the award of a Baronetcy in 1866. He died in 1870 and a Westminister Abbey burial was offered to his family, but this was refused and he was buried in Warriston cemetery, Edinburgh, beside the children who had predeceased him. On the day of the burial a service was held at his home for family and friends, and many other services were held around the city. Afterwards the crowds converged on Simpson's home, where a funeral procession a mile long and involving 2000 people was organized. A crowd estimated at 80 000 watched it pass.[8] Despite this large show of public grief, Simpson was obviously not liked by all. No one achieves so much without ambition, and ambition can be a negative in addition to a positive force. His obituary in the *British Medical Journal* makes interesting reading and clearly was not written by a supporter. It states that his greatest work was the attempt to diminish the mortality of surgical hospitals, although it concedes that "he may claim the chief share of whatever credit belongs to the recommendation of the general employment of anaesthesia in midwifery practice" and "the position of JYS in reference to anaesthetics may be easily stated. He had, of course, no claim whatever to their introduction, nor is it probable that their general acceptance would have waited for his advocacy of their claims".[9] A case of damning by faint praise if ever there was one!

What lay behind this already successful physician, his commitment to anaesthesia and his involvement with the ensuing controversy over its use? Fundamentally he was a humane man who believed the object of the medical practitioner to be "the alleviation of human suffering and the preservation of human life". This lead him to try and improve the lot of his patients, whether by attempting to decrease postoperative inflammation or providing analgesia during labour. Fortunately, and unlike many physicians, he had the imagination to perceive that improvements in medical care could be made, and the forceful personality required to initiate them. His greatest achievement must be publicizing anaesthesia and challenging opponents so that it became accepted; 150 yr on it is impossible to imagine anyone having a career with so many different facets and achieving so much. Not only did he also have a happy family life, but he even found time to be a successful amateur archaeologist, becoming President of the Society of Antiquaries of Scotland in 1861.[1] It seems very likely that if James Young Simpson were alive today he would be at the forefront of progress and development while still making time for, and enjoying, his family and private life.

EDITORIAL II

Propofol in paediatric intensive care

The need for sedation in paediatric intensive care is well recognized, both for spontaneously breathing children and those undergoing mechanical ventilation, with or without neuromuscular blocking agents. The level of sedation required varies with the pathology, but a survey of paediatric intensive care units in the UK in 1991, published in 1993, showed that most respondents favoured i.v. infusion as the method of choice for drug delivery.[1] Although a wide variety of sedative and analgesic agents have been used, reliance has traditionally been placed on opioid and benzodiazepine drugs. These have several disadvantages, including prolonged action and acute withdrawal symptoms. Almost none of the agents commonly used in adult intensive care is licensed for long-term infusion in children. Isoflurane has been used in some units, although it is expensive, its use requires the installation of scavenging facilities and concerns remain about fluoride toxicity.

After successful use in adults, the first case report describing an infusion of propofol for paediatric sedation appeared in 1987 with further reports appearing shortly afterward.[2–4] After these initial reports, the technique became increasingly popular despite the fact that propofol was not licensed for use in this situation. Although early reports suggested that infusion rates of less than 50 μg kg^{-1} min^{-1} gave acceptable sedation with rapid recovery and no undesirable side effects, almost all subsequent investigators have used much higher doses than those recommended in adults (1–4 mg kg^{-1} h^{-1}).

Reports of serious complications began to appear in the early 1990s, and appear to fall into two distinct categories. There have been several reports of signs of central nervous system irritability on withdrawal of propofol,[5–7] similar signs having been reported previously with midazolam and fentanyl.[8] More seriously, the Danish Side Effects Committee drew attention to the death of a 2-yr-old child with croup who developed hypotension, hepatomegaly and multi-organ failure after administration of propofol 10 mg kg^{-1} h^{-1} for 4 days.[9] In 1992, Parke and colleagues reported five deaths in children who had received propofol infusions lasting several days during intensive care for upper respiratory tract infections.[10] All children developed lipaemic serum, severe metabolic acidosis, hepatomegaly and multi-organ failure. After these reports, the Committee on Safety of Medicines in the UK issued a serious adverse effects warning which led to the virtual abandonment of propofol as a sedative in most paediatric intensive care units in the UK. However, two deaths were reported in Norway,[11] and five similar cases have been reported throughout the world.[12–16] Pulmonary hypertension and rhabdomyolysis have also been reported.[17] In all cases maximum infusion rates exceeded 6 mg kg^{-1} h^{-1}, and all deaths except one occurred in patients with respiratory infection. Even this child had radiographic evidence of atelectasis and tracheal secretions grew *Haemophilus influenzae.* As she had been receiving large doses of steroids for 36 h before developing metabolic acidosis, septic shock cannot be excluded.[15]

Several possible mechanisms have been suggested for these deaths, including extrinsic bacterial contamination of propofol or hypertriglyceridaemia in the presence of impaired lipid metabolism. There is clear evidence that children receiving parenteral nutrition are at an increased risk of infection,[18] possibly as a result of increased microbial translocation of intestinal micro-organisms, although in almost all cases this is associated with cholestasis and increased serum bilirubin concentration.[19] Another suggestion is that some host factor may be responsible by the inclusion of viral DNA into an already susceptible genotype. Some have drawn attention to the similarities to the changes seen in malignant hyperthermia and Reye's syndrome.

Although the case reports and adverse effects warnings have undoubtedly had a significant impact throughout the world, propofol is still being used extensively for intensive care sedation in children, especially in North America. The published literature describes its use in more than 300 children from less than 1 to 12 yr of age for periods of up to 2 weeks with infusion rates, where stated, of 0.44–26.3 mg kg^{-1} h^{-1} without serious side effects. It appears to be used in almost all of the 144 paediatric intensive care units in the USA, particularly during weaning from ventilatory support or during transition from sedation with other drugs to awareness. It is also used in children with head injuries who require periodic awakening for assessment. Although many centres restrict its use to periods of up to 48 h or limit the amount of propofol infused, in others no such restrictions are applied. Reed and Blumer in Cleveland have challenged the causal relationship between propofol administration and the development of metabolic acidosis,[20] and have used the drug in more than 500 cases without serious complications. They have also used propofol continuously for up to 3 months. Surprisingly, the United States Food and Drugs Authority has issued no warning about its use and in fact its Advisory Committee on Anaesthetic and Life Support Drugs stated in 1992 that "propofol has no direct link to paediatric deaths in hospital intensive care units and no identifiable cardiac adverse events in children and adults". The manufacturers however issued a warning against its use for continuous sedation of paediatric intensive care patients.

In an article published in this issue of the *British Journal of Anaesthesia,* Martin, Murthy and Petros[21] have revisited this difficult issue. Their study investigated the metabolic, biochemical and haemodynamic effects of propofol infusion (up to 4 mg kg^{-1} h^{-1}) in nine sedated children studied for 48 h after cardiac surgery. The children's lungs were ventilated to mild hypocapnia, had no evidence of respiratory tract infections and were not receiving parenteral nutrition containing additional Intralipid. There was no evidence of metabolic acidosis or significant alterations in serum urea, creatinine, glucose or triglyceride concentrations from baseline values. Liver enzymes did not increase significantly during this period and no ketones were detected in urine. The authors concluded that propofol infusions can be used safely in postoperative cardiac patients if strict guidelines are followed, and they support the call for properly conducted clinical studies to re-evaluate its use in paediatric intensive care. Review of the published literature would suggest that children with existing sepsis or primary respiratory problems should probably be excluded from such research, and that infusion rates should be kept to those used in adults, even if other drugs have to be used to ensure adequate sedation. Large studies are required before criteria for the safe use of propofol in paediatric intensive care can be defined.

CLINICAL INVESTIGATIONS

Metabolic, biochemical and haemodynamic effects of infusion of propofol for long-term sedation of children undergoing intensive care

P. H. MARTIN, B. V. S. MURTHY AND A. J. PETROS

Summary

We have studied prospectively, in nine children requiring sedation to facilitate mechanical ventilation, the metabolic, biochemical and haemodynamic effects of infusion of propofol. Children were given infusions of propofol 1–4 mg kg^{-1} h^{-1} and fentanyl 1–5 μg kg^{-1} h^{-1} for 48 h. Heart rate, arterial pressure, central venous pressure, fluid balance and urine output were recorded hourly and sedation scores every 4 h. In addition to routine haemodynamic and biochemical measurements in the intensive care, 6-hourly arterial blood-gas analysis and 12-hourly measurements of serum concentrations of glucose, lactate and electrolytes, renal function, triglycerides and liver function tests were performed. Urine was analysed for ketones. There were no significant differences in haemodynamic or biochemical variables during the 48-h period. In this small sample of children, propofol combined with fentanyl provided excellent sedation with no evidence of cardiac, renal or hepatic impairment. Under these very proscriptive conditions we did not encounter lipaemia or acidosis with infusion of propofol. Thus propofol may be a safe sedative agent for use in paediatric intensive care if used appropriately. Further large scale studies are needed to determine if warnings against the use of this agent in paediatric intensive care units are justified. (*Br. J. Anaesth.* 1997; **79**: 276–279).

Key words
Anaesthetics i.v., propofol. Sedation Intensive care, sedation. Anaesthesia, paediatric.

As the use of propofol becomes more widespread in adult intensive care units,[1 2] the reported deaths of seven children[3–5] who received propofol for sedation as part of their intensive care management is of considerable concern. The children aged between 4 weeks and 9 yr who required mechanical ventilation for severe upper respiratory tract infections developed lipaemia and metabolic acidosis before death. Although no causal relationship was established, the Committee on Safety of Medicines issued a serious adverse effects warning leading to the immediate abandonment of propofol as a sedative agent in the paediatric intensive care unit.[6]

The aim of this open prospective study was to investigate the effects of a sedative infusion regimen of propofol on the metabolic, biochemical and haemodynamic changes in a group of children without upper respiratory tract infections over a 48-h period. Propofol was used in combination with fentanyl at low doses and under very specific conditions to facilitate ventilation in a group of children in a cardiac surgical intensive care unit for a predetermined period.

Patients and methods

This study was approved by the Ethics Committee of the Royal Liverpool Children's NHS Trust. Parents were fully informed of the current concerns about the use of propofol in children. They were also made aware of the case report of the five deaths and given an information sheet describing these issues in simple terms. An Exemption from Licences of the Medicine Special Cases and Miscellaneous Provisions Order 1972 was also obtained from the Medicines Control Agency.

Nine child needing sedation to facilitate mechanical ventilation after cardiac surgery or weaning from ventilation were considered eligible for the study. Mean arterial pressure was monitored invasively via an indwelling arterial cannula in all children, and in five children central venous pressure was monitored. Concurrent sedatives were stopped and infusions of propofol 1–4 mg kg^{-1} h^{-1} and fentanyl 1–5 μg kg^{-1} h^{-1} were commenced without loading boluses. Neuromuscular blocking agents were not given. Sedation was scored every 4 h.[7] Bolus doses of propofol and fentanyl, equivalent to 25% of the current hourly infusion rate, were given during interventions such as tracheal suctioning or physiotherapy. Propofol was continued for 48 h or until the child was considered ready for tracheal extubation, if sooner. The lungs were ventilated to mild hypocapnia with oxygen-enriched air and inotropic support was continued according to clinical requirements. Heart rate, arterial pressure, central venous pressure, fluid

This article is accompanied by Editorial II.

input and urine output were recorded hourly. Parenteral nutrition containing Intralipid was avoided. In addition to hourly cardiovascular and respiratory observations made in the ICU, 6-hourly arterial blood-gas analysis and 12-hourly measurements of serum concentrations of electrolytes, urea, creatinine, glucose, lactate, triglycerides, total bilirubin, γ-glutamyltransferase (GGT), aspartate aminotransferase (AST), alanine aminotransferase (ALT) and alkaline phosphatase were made (Axon Clinical Chemistry Analyser, Bayer Diagnostics, UK).[8] Age specific normal ranges generated within our laboratory were used for comparisons. Urine was collected 12-hourly and analysed for ketones and organic acids.

Statistical analysis was performed using the Kruskal–Wallis non-parametric ANOVA test. All values are expressed as mean (95% confidence interval (CI)). $P<0.05$ was considered statistically significant.

Results

Nine children (four males) completed the study. One child required a second episode of ventilation, 2 months later, after developing left upper lobe pulmonary consolidation resulting in 10 episodes of propofol infusion. Median age was 19 months (95% CI 2.2–104.7 months) and mean weight 13.9 (2.8–25.0) kg. The trachea of one child was extubated within 24 h and in two children, propofol infusion was continued for clinical reasons for 84 h and 144 h with no adverse effects. Five children with Down's syndrome had atrioventricular septal defect (AVSD) repair, three had complete repair of tetralogy of Fallot and one had a tracheal stent insertion for tracheomalacia. The mean dose of propofol infusion was 2.1 (1.5–2.8) mg kg^{-1} h^{-1} and mean duration of infusion was 35.3 (33–87) h.

SEDATION

All children were considered adequately sedated. Mean baseline sedation score was 4.2 (1.3–3.2), and was 4.25 (3.3–5.2) at 12 h, 4.0 (3.2–4.9) at 24 h, 3.0 (2.4–3.6) at 36 h and 3.2 (2.4–4.0) at 48 h. There was no significant difference in sedation scores during the 48-h study compared with baseline recordings. No child required additional sedative or neuromuscular blocking agents.

CARDIOVASCULAR EFFECTS

During the 48 h of the propofol infusion there were no significant changes in heart rate, mean arterial pressure or central venous pressure. Mean baseline heart rate was 120 (94–167) beat min^{-1}, and 123 (99–160) beat min^{-1} at 12 h, 116 (89–158) beat min^{-1} at 24 h, 128 (107–155) beat min^{-1} at 36 h and 131(115–149) beat min^{-1} at 48 h. Mean baseline arterial pressure was 53 (35–73) mm Hg, and 55 (31–71) mm Hg at 12 h, 56 (49–68) mm Hg at 24 h, 56 (40–72) mm Hg at 36 h and 61 (41–80) mm Hg at 48 h. Mean baseline central venous pressure was 7 (4–9) mm Hg, and 7 (4–10) mm Hg at 12 h, 6 (4–7) mm Hg at 24 h, 7 (4–9) mm Hg at 36 h and 6 (4–7) mm Hg at 48 h. No arrhythmias were noted and in particular no episodes of bradycardia.

METABOLIC AND BIOCHEMICAL EFFECTS (TABLE 1).

Based on a mean infusion rate of 2.1 mg kg^{-1} h^{-1}, mean total lipid load provided by the 10% Intralipid emulsion in which propofol is suspended was 0.45G lipid kg^{-1} day^{-1}. No gross lipaemia was observed on direct visual inspection in any of the blood samples obtained. Although serum triglyceride concentrations were increased above the normal range quoted for our laboratory at 12 h, 24 h and 36 h, there were

Table 1 Metabolic and biochemical changes during the 48-h infusion of propofol (mean (95% confidence interval)). There were no significant differences in any variable at any time during the study. (Nine children were studied but one child was sedated twice, separated by a period of 2 months, making 10 clinical episodes)

(187–1197 iu litre^{-1})	(173–551)	(183–440)	(224–561)	(221–450)	(224–635)

no significant differences from baseline. There was no evidence of lactic acidosis within the 48-h period, with the highest mean value of 1.78 mmol litre^{-1} occurring at 48 h. There were no significant changes in pH, bicarbonate or base deficit which remained positive throughout the period of infusion. Plasma concentrations of urea and creatinine did not change significantly from baseline, in common with serum glucose concentrations. The hepatic enzymes, AST, ALT and GGT did not increase significantly during the 48 h. No ketones were detected in any of the urine samples.

Discussion

Adequate sedation and analgesia is an integral part of intensive care management. Infusions of midazolam, propofol, fentanyl and alfentanil are used commonly in adult intensive care. However, the last available survey in 1991 of PICU in the UK revealed that at that time the majority were using these sedatives outside their product licenses.[9]

The pharmacodynamics and pharmacokinetics of propofol make it ideal for maintenance of prolonged sedation of patients undergoing mechanical ventilation in the ICU. Propofol has been studied extensively in adult intensive care, where it has been shown to provide satisfactory sedation and rapid recovery with minimal side effects.[10–13] In contrast, there is little published information on the clinical use of propofol in critically ill children.[14 15] The case report of five deaths in children with upper respiratory tract infections described propofol infusions at concentrations varying from 4 mg kg^{-1} h^{-1} to a short maximum rate of 13.6 mg kg^{-1} h^{-1} for 8 h.[3] Even for this relatively short period, the equivalent infusion rate for a 70-kg adult would be 95.2 ml h^{-1} giving a total volume of 762 ml in the 8-h period. The doses used in our study (mean 2.1 mg kg^{-1} h^{-1}) were much lower and equivalent to approximately 15 ml h^{-1} for a 70-kg adult, which is a more generally acceptable rate of infusion used in adult intensive care. Parke and colleagues[3] acknowledge that propofol contains 0.1 g of lipid per millilitre and that 10% Intralipid from the propofol infusion might have contributed to the deaths. They calculated that even at the maximum rates of propofol infusion used, less than half of the recommended infusion rate of 10% Intralipid in infants was given (Intralipid data sheet, Pharmacia, Milton Keynes, UK) and therefore the lipid content of propofol was unlikely to be the sole cause of the deaths. However, it is not clear if the five infants also had supplementary parenteral nutrition and how much Intralipid was prescribed in addition to that received from the propofol infusion. As lipid metabolism may be impaired in children with sepsis, the authors were correct in observing that added lipid load from propofol may have contributed to the lipaemic serum noted. They were also correct to point out that infusions of lipid should be minimized and triglyceride concentrations monitored carefully in septic children.

Several other case reports suggest that there may be a syndrome of propofol associated metabolic acidosis (PAMA) which is idiosyncratic in incidence. The syndrome appears to include metabolic acidosis, hypercapnia and hyperthermia, resulting in hypotension unresponsive to vasopressors and broad complex bradycardia unresponsive to chronotropes or mechanical pacing.[5] This has led some to speculate that this syndrome is similar to that of malignant hyperthermia.[16] The picture of a previously healthy child admitted with a trivial URTI or minor neurological symptoms who suddenly and unexpectedly dies after administration of a specific agent has led others to draw similarities with the discovery of aspirin producing Reye's syndrome in children. Unfortunately, there are no data available in terms of number of patient days over which propofol was infused to allow an estimate of the incidence of PAMA and there are still many unanswered questions. If PAMA is an idiosyncratic response why is it seen only in children receiving infusions and not in those who receive propofol for induction of anaesthesia? All the reports of PAMA are in infants and young children; is this a maturational problem in relation to lipid load? Why is PAMA not seen in adults receiving infusion of propofol; is it being missed because deaths from cardiac arrhythmias are more explicable in an adult population?

In 1992 the United States Food and Drugs Authority advisory committee (Anesthetic and Life Support Drugs) concluded that propofol has no direct link to paediatric deaths in hospital intensive care units and no identifiable link to adverse cardiac events in children and adults[17]. A recent study in 28 children has defined the pharmacokinetics of propofol and recommended a dose regimen to maintain optimal sedation which requires a serum concentrations of 1 mg litre^{-1}. The regimen varies with time, starting at infusion rates of 7.5 mg kg^{-1} h^{-1} and decreasing to 4.3 mg kg^{-1} h^{-1} over 4 h.[18] We recommend a much lower dose of 2.1 mg kg^{-1} h^{-1}. This difference in dose rates probably results from our concomitant use of an opioid, which contributed to lower propofol requirements. When used under the specifically controlled circumstances such as those we have described in appropriately monitored and resuscitated children, we believe that propofol sedation has a valuable role in paediatric intensive care. In our practice we have found propofol to be particularly useful in allowing rapid changes in sedation levels and so facilitating ventilation and weaning. Although we have studied only a small number of children we could find no evidence of progressive acidosis or significant metabolic or biochemical derangements.

We have demonstrated that in this small group of children without respiratory disease and not receiving parenteral nutrition, sedation with propofol caused no significant haemodynamic, metabolic or biochemical changes. In no instance did the infusion rate have to be reduced from that dictated by the study design because of adverse haemodynamic effects. No significant changes in blood lactate concentrations occurred, indicating adequate tissue oxygenation. Our findings support those of a similar study in 10 critically ill adults receiving propofol infusions (2–4 mg kg^{-1} h^{-1}). No significant changes in global oxygen transport and delivery, lactate concentration and cardiac output were noted, and there was no evidence of lipaemia or triglyceridaemia,[13] although the adult liver may be better able to handle lipids in sepsis.

We conclude that propofol may be used in post-operative cardiac patients in the doses recommended and in combination with an opioid. We found that propofol was useful in sedating children with Down's syndrome who are often confused on emerging from sedation. We agree with those who request correctly conducted clinical studies to re-evaluate the use of propofol infusions in children.[15] However, despite enthusiasts such as Reed and Blumer declaring, "propofol bashing: the time to stop is now"[19] we still have several reservations about its indiscriminate use in sick children. We recommend that until more information is available on the incidence of PAMA and its precipitating factors, propofol should not be administered to children who are suffering from an acute infective process, particularly an upper respiratory tract infection; it should not be used as the sole sedative agent; it should not be infused at greater than 5 mg kg^{-1} h^{-1}; and its continued use should be reviewed daily.

Comparison of sevoflurane and halothane for outpatient dental anaesthesia in children

S. T. PARIS, M. CAFFERKEY, M. TARLING, P. HANCOCK, P. M. YATE AND P. J. FLYNN

Summary

In a prospective, randomized, double-blind clinical study, we have studied 100 children, aged 2–12 yr, to compare halothane and sevoflurane in outpatient dental anaesthesia. All patients were unpremedicated and received inhalation induction using nitrous oxide in oxygen supplemented with either halothane (maximum inspired concentration 5%) or sevoflurane (maximum inspired concentration 8%). Time to loss of the eyelash reflex was more rapid using sevoflurane although time to adequate anaesthesia (to allow insertion of a mouth prop) was slower in the sevoflurane group. The incidence of cardiac arrhythmia was higher during halothane (62%) than during sevoflurane anaesthesia (28%) ($P<0.005$) and the arrhythmias were more often ventricular in origin. The two agents were comparable in terms of ease of use and quality of anaesthesia, and times to eye opening and satisfying discharge criteria were similar. We conclude that sevoflurane has qualities that have made halothane the most used inhalation agent for children, and that it is superior to halothane in dental outpatients where cardiac arrhythmias are a particular problem. (*Br. J. Anaesth.* 1997; **79**: 280–284).

Key words
Anaesthetics volatile, halothane. Anaesthetics volatile, sevoflurane. Surgery, dental. Children.

It is becoming increasingly apparent that sevoflurane has the potential to be the inhalation induction agent of choice in children.[1–4] It is relatively pleasant smelling, non-irritant and has a rapid onset and offset of action by virtue of its low blood-gas solubility.

Halothane is still used widely in paediatric dental outpatient anaesthesia as it is relatively non-pungent and provides smooth induction and recovery. Its main disadvantages are a strong odour, cardiovascular depression, a propensity to cause arrhythmias and rarely hepatic necrosis, especially after repeated exposures. During dental surgery, the incidence of arrhythmia during halothane anaesthesia has been reported to be as high as 75%.[5] The use of enflurane or isoflurane reduces the incidence of arrhythmias during oral surgery but both are inferior to halothane in terms of ease of induction and quality of anaesthesia.[5–7] This study was designed to compare the incidence and type of arrhythmia, and quality of anaesthesia and recovery during sevoflurane and halothane anaesthesia in children undergoing outpatient dental extraction.

Patients and methods

After obtaining Ethics Committee approval and written parental consent, we studied 100 unpremedicated children, ASA I–II, aged 2–12 yr, undergoing outpatient dental extractions under general anaesthesia; patients were allocated randomly to one of two groups to receive either sevoflurane or halothane.

Electrocardiographic limb leads were attached to the patient before induction of anaesthesia and a continuous record of lead II was obtained together with a visual oscilloscope display. A paediatric pulse oximetry probe was applied before induction of anaesthesia and oxygen saturation (Sp_{O_2}) was monitored continuously throughout surgery and during recovery from anaesthesia. Arterial pressure readings before and after induction were obtained whenever possible and recorded. The time of induction, placement of the mouth prop, dental extractions and discontinuation of anaesthetic were recorded by a blinded observer who also assessed the incidence of complications during anaesthesia and recovery. Complications were graded on a scale from 0 to 3: 0=not present; 1=present but not troublesome; 2=causing interference with technique or requiring treatment; 3=so troublesome that technique had to be abandoned or patient needed admission to hospital. Complications assessed were intolerance to the vapour, breath-holding, coughing, salivation, laryngospasm, vomiting, Sp_{O_2} <90%, rigidity, excitatory movements and shivering. In the recovery area, times to eye opening to command and to "street fitness" (able to drink and walk around the recovery area unaided) were also recorded.

Dental extractions were carried out in the supine position and anaesthesia was administered by one

Duration of surgery (min)	2.53 (0.3–9.2)	1.91 (0.4–9.9)
Duration of anaesthesia (min)	6.72 (2.5–12.8)	5.58 (2.9–13.7)

of three consultant anaesthetists with extensive experience of the technique. Anaesthesia was induced by inhalation of 50% nitrous oxide in oxygen with the selected vapour introduced in increments of 1% to a maximum of 5% halothane, and in increments of 2% to a maximum of 8% sevoflurane. The concentration of the agents was increased every 3–5 breaths or more rapidly if tolerated by the patient. Sevoflurane and halothane were administered via recently calibrated vaporizers (Blease-Datum, TEC 3 Ohmeda). The vapour was delivered by a Bain system with the anaesthetist holding the patient end of the system as close to the child's face as possible. Fresh gas flow rates were always in excess of 200 ml kg^{-1} min^{-1}. When the child lost consciousness, a nasal mask was applied and anaesthesia was maintained with 50% nitrous oxide in oxygen and the selected vapour. Maintenance concentrations of sevoflurane were 2–4% and 1–2 % for halothane. Anaesthetic gases were discontinued at the time of extraction of the penultimate tooth. The child was given 100% oxygen and at completion of the procedure was turned to the left lateral, head-down position. Transfer to the recovery area occurred when the patient had a patent airway, acceptable respiratory pattern and normal oxygen saturation, and any cardiac arrhythmia had resolved.

ECG recordings were analysed by a physician who was unaware of the anaesthetic agent used. These were analysed over three times: induction (time from gases on to commencement of surgery), surgery (end of induction to discontinuation of nitrous oxide and anaesthetic vapour) and recovery (end of surgery to discharge from the operating theatre).

Data are presented as mean (SD) or median (95% central ranges) unless otherwise stated. Statistical analyses were performed using the Mann–Whitney *U* test, Fisher's exact test or the chi-square analysis, as appropriate. $P<0.05$ was considered statistically significant.

Results

Data from 100 children (50 in each treatment group) were collected and analysed. Patient characteristics and clinical data, including duration of anaesthesia and surgery, and extent of surgery, were similar in the two groups (table 1). No patient was excluded during the study.

HEART RATE AND ARTERIAL PRESSURE

The incidence of heart rate decreasing to less than 80 beat min^{-1} was similar in both groups (sevoflurane group 16%, halothane group 14%) and no patient required treatment. Mean maximum heart rate was significantly higher in the sevoflurane group (146 beat min^{-1}) than in the halothane group (138 beat min^{-1}) (P=0.019).

It was possible to obtain systolic arterial pressure measurements before and after induction of anaesthesia in 75 patients. In the sevoflurane group there was a mean decrease of 1.6 (SD 17.7) mm Hg; in the halothane group there was a mean decrease of 9.4 (17.7) mm Hg. This difference was not statistically significant (P=0.061).

ARRHYTHMIAS

All arrhythmias (table 2)

The overall incidence of arrhythmia was significantly greater in the halothane group (62% *vs* 28%) (P<0.0005). During induction, more patients in the halothane group had arrhythmias, although this difference was not statistically significant. During surgery, 44% of patients anaesthetized with halothane had arrhythmias compared with 24% given sevoflurane (P=0.035), whereas during the initial recovery period the values were 30% and 6%, respectively (P=0.002).

Supraventricular arrhythmias

The incidence of premature atrial beats and AV junctional rhythm did not differ significantly between the two groups (table 3).

Ventricular arrhythmias.

Single premature ventricular beats (PVB) occurred in 25 patients in the halothane group and in 11

Table 2 Incidence of arrhythmia during anaesthesia

	Throughout	Induction	Surgery	Recovery
Halothane (%)	62	20	44	30
Sevoflurane (%)	28	10	24	6
P	<0.0005	0.161	0.035	0.002

Table 3 Classification and incidence of arrhythmias observed. Data are number of patients in whom the arrhythmia was seen. (PVB=Premature ventricular beats)

	Sevoflurane (n=50)	Halothane (n=50)	P
Premature atrial beats	5	7	0.538
AV junctional rhythm	2	6	0.269
Occasional PVB	11	25	0.004
Bigeminy	0	15	<0.0005
Episodes of PVB <10 beats	3	11	0.021
Episodes of PVB >10 beats	0	2	0.153
Ventricular tachycardia	0	1	0.315

patients in the sevoflurane group (P=0.004). Bigeminy occurred only in the halothane group, in 15 patients (P<0.0005).

Eleven patients anaesthetized with halothane had episodes of multifocal ventricular ectopics which occurred during all three phases of anaesthesia. This arrhythmia occurred in only three patients in the sevoflurane group (P=0.021) (table 3), and in each case the episode of PVB was not longer than 4 beats. In the halothane group two patients had episodes of PVB of more than 10 beats and one patient had three episodes of ventricular tachycardia which were self-terminating.

QUALITY OF ANAESTHESIA

The technique did not have to be abandoned in any patient and therefore grade 3 of the complication score was not included in the statistical analysis.

Induction and recovery times (table 4)

The time between start of induction and loss of eyelash reflex was significantly shorter in the sevoflurane group (mean 1.5 (SD 0.6) min) compared with the halothane group (1.9 (0.5) min). However, time to insertion of the mouth prop was significantly slower after induction with sevoflurane (3.9 (1.3) min in the sevoflurane group *vs* 3.5 (0.7) min in the halothane group).

In the recovery period, times to eye opening and discharge were similar in both groups (table 4).

Table 4 Induction and recovery times for sevoflurane and halothane anaesthesia. Data are mean (SD)

	Induction (time (min) from gases on)		Recovery (time (min) from gases off)	
	Loss of eyelash reflex	Insertion of mouth prop	Eye opening	Fit for discharge
Sevoflurane (n=50)	1.5 (0.6)	3.9 (1.3)	7.3 (2.3)	23.0 (5.6)
Halothane (n=50)	1.9 (0.5)	3.5 (0.7)	7.8 (2.9)	23.2 (5.4)
P	0.0003	0.04	0.325	0.875

	2	—	—		—	—		0	0	

Complications

The incidences of intolerance, airway reflex responses, hypoxaemia (Sp_{O_2} <90%), vomiting and shivering were similar between the two groups.

Nine patients in the sevoflurane group demonstrated rigidity during induction compared with two in the halothane group (*P*=0.026), but this was not severe enough to interfere with the technique (table 5).

During the recovery period, the incidence of excitatory movements on emergence was significantly higher in the sevoflurane group (*P*=0.038).

Discussion

Inhalation anaesthesia is used widely for induction in paediatric outpatient dental surgery. Halothane is still the agent favoured by most anaesthetists in this clinical situation, but its main problems are its propensity to cause cardiac arrhythmia, and the risk, albeit rare, of fulminant hepatitis on repeated exposure. The incidence of arrhythmia in patients undergoing dental surgery during halothane anaesthesia has been reported as high (75%).[8] In our study we found that 62% of patients had arrhythmias during anaesthesia with halothane compared with only 26% of patients given sevoflurane.

The significance of arrhythmias during anaesthesia for oral surgery with respect to anaesthetic mortality has yet to be established. However, the incidence of unexplained deaths in dental anaesthetic mortality reports[9 10] and evidence from recent coroners' inquests suggest that they cannot be ignored. In this study the incidence of arrhythmia during induction and surgery in the halothane group was approximately double that in the group receiving sevoflurane. It was notable that during the recovery period 30% of patients given halothane had arrhythmias compared with only 6% after sevoflurane. Coplans and Curson found that more than 50% of deaths associated with dentistry occurred during the recovery period.[9] Sevoflurane may offer an increased safety margin in dental anaesthesia because of its low propensity to cause arrhythmias, but also because the associated arrhythmias are predominantly supraventricular in type. Analysis of the recordings showed that ventricular arrhythmias were found almost exclusively in the group receiving halothane. While it is not known which arrhythmias associated with anaesthesia are significant, it is generally accepted that arrhythmias which are ventricular in origin carry a higher risk. The incidence of arrhythmia in association with oral surgery was found to be much lower when enflurane (10%) and isoflurane (14%) were used.[5 6] As with sevoflurane, ventricular ectopy was almost uniformly absent, but neither enflurane nor isoflurane offered equivalence in terms of facility of induction to halothane.

We found that sevoflurane and halothane were similar in terms of "smoothness" and quality of anaesthesia overall. The higher incidence of rigidity during induction with sevoflurane was not severe enough to interfere with anaesthesia. Excitatory phenomena during this phase have been reported previously with this agent.[4 11 12] Agitation and restlessness during recovery were also more frequent after sevoflurane and were noted by other investigators.[1 13] The most likely explanation is that patients are experiencing rapid emergence as the agent is eliminated rapidly.

In view of the lower blood-gas partition coefficient of sevoflurane, it would be expected to provide more rapid inhalation induction than halothane.[13–15] However, the rate of inhalation induction of anaesthesia is also determined by potency, maximum deliverable inspired concentration (limited by the vaporizer used) and the rate of increase of the inspired concentration. In our study no attempt was made to match the two groups in terms of equivalent MAC multiples of the volatile agents during induction, as in several recent comparative studies.[1 14 16 17] Within the confines of our study we confirmed that the time to loss of the eyelash reflex was indeed shorter with sevoflurane, but the time required to achieve the depth of anaesthesia that would allow insertion of a mouth prop was marginally, but significantly, longer compared with halothane. Black and co-workers[15] recently compared induction times in paediatric patients using a method similar to that described in this study and still found a shorter induction time with sevoflurane than with halothane. However, the end-point for completion of induction was the time to steady spontaneous ventilation with small pupils and central gaze. We found that these criteria did not always correspond to a plane of anaesthesia deep enough to allow insertion of a mouth prop for dental surgery. Furthermore, Sarner and colleagues[4] recently compared times to intubation during sevoflurane and halothane anaesthesia and showed that the two were almost identical. It seems that while induction of anaesthesia is more rapid with sevoflurane, the time needed to achieve deeper planes of anaesthesia is similar to that with halothane. The maximum concentrations of the agents that we could deliver were 5% halothane and 8% sevoflurane. In this age group, these correspond to approximately 5 MAC and 4 MAC, respectively; this suggests that part of the limitation of induction time for sevoflurane may be a function of the vaporizer. In addition, sevoflurane is more of a respiratory depressant than halothane at concentrations greater than 1.4 MAC,[18] so that at deeper planes of anaesthesia uptake of the vapour may be slower than halothane and this may also make induction relatively slower.

We did not find any difference in the rate of emergence and full recovery, unlike recent studies showing that recovery from sevoflurane anaesthesia was more rapid, as would be expected from its lower blood-gas solubility.[14 17 19] However, the duration of anaesthesia required for outpatient dental surgery is very short and in these circumstances halothane would not be expected to have a prolonged recovery period.

Comparison between halothane and sevoflurane for adult vital capacity induction

J. E. HALL, T. A. OLDHAM, J. I. M. STEWART AND M. HARMER

Summary

We have examined the differences in ventilatory characteristics between halothane and sevoflurane when used for adult vital capacity induction of anaesthesia. The study was conducted in a randomized, double-blind manner. After 13 patients had been enrolled, the study was curtailed because the blinded observer thought that there was an unacceptably high incidence of adverse events. After the randomization code was revealed, the adverse events were found to be in the halothane group. Although the sample size was small, minute volumes appeared to be maintained in the sevoflurane group. Ventilatory frequencies were similar in the two groups after insertion of the laryngeal mask airway, but tidal volumes were significantly greater in the sevoflurane group (P=0.0013). (*Br. J. Anaesth.* 1997; **79**: 285–288).

Key words
Anaesthetic techniques, induction. Anaesthetics volatile, sevoflurane. Anaesthetics volatile, halothane. Ventilation, anaesthetics, effects of.

In the course of a recently completed study in which sevoflurane was used for adult gaseous induction,[1] it was noticed that the technique appeared to be associated with tachypnoea[2] of a magnitude not reported previously. Tachypnoea appeared to be responsible for very rapid deepening of anaesthesia and it was postulated that this was associated with an increase in tidal volume. If this is the case, it would appear that sevoflurane used in this way stimulates respiration at these concentrations, although this could be technique- and not agent-specific.

Although vital capacity induction has been attempted with all currently available volatile agents, including irritant agents such as isoflurane,[3] it has been studied most extensively with halothane.[4–6] This study was undertaken in adults to compare the ventilatory characteristics during high concentration gaseous induction using sevoflurane and halothane.

Patients and methods

Approval for the study was obtained from the local Research Ethics Committee. It was planned to recruit to the study 24 ASA grade I and II patients of both sexes, aged 18–65 yr, undergoing day-case orthopaedic surgery.

Exclusion crtieria were: patients receiving (either acutely or chronically) any drugs that might alter the minimum alveolar concentration of the volatile agent, those with a body mass index >1.5 times normal, those who had received halothane anaesthesia in the previous 3 months, were receiving enzyme-inducing drugs or in whom it was anticipated that large amounts of adrenaline-containing local anaesthetics would be used during operation. The study was randomized and double-blind. All observations were made by a single-blinded investigator (J. E. H.) and all inductions were performed by two anaesthetists familiar with the vital capacity induction technique (T. A. O. and J. I. M. S.). Patients were unpremedicated. The vital capacity technique was explained to patients during the preoperative visit. In the anaesthetic room, patients were allocated to one of two groups.

Group 1. Patients' lungs were preoxygenated from a Mapleson C breathing system which was supplied from a separate oxygen source in the anaesthetic room. After preoxygenation, patients were instructed to expire to residual volume. During this time the breathing system was changed to a prefilled Mapleson A breathing system with a 4-litre reservoir bag. Patients then took a vital capacity breath of the gaseous induction mixture which they held for as long as possible. When they could not hold their breath anymore, they were allowed to breathe normally. The induction mixture consisted of 8% sevoflurane (dial concentration) and 66% nitrous oxide in oxygen, with a total fresh gas flow of 6 litre min^{-1}. End-tidal volatile concentrations at the distal end of the system were measured using a Capnomac Ultima monitor (Datex, Helsinki, Finland), and filling of the Mapleson A system was commenced when the monitor indicated a concentration greater than 7.5%. Timing of induction commenced from the start of inhalation after expiration to residual volume.

Correspondence to J. E. H.

Group 2. Induction proceeded as in group 1 but 4 % halothane (dial concentration) was used. Filling of the Mapleson A system commenced when the monitor indicated a concentration greater than 3.5%.

In both groups, jaw relaxation was tested every 30 s after loss of the eyelash reflex. When this was achieved, a laryngeal mask airway was inserted. Patients continued to breathe the same concentration of volatile agent for 2 min after insertion of the laryngeal mask airway, after which the anaesthetist was allowed to proceed with an anaesthetic appropriate to the surgical procedure. Any adverse airway events during induction were treated in a manner that was thought appropriate by the anaesthetist.

The vaporizer was draped. The observer wore two face masks to eliminate the smell of the volatile agents and entered the anaesthetic room only when induction was about to commence. The agent indicator and its scale on the agent monitor were covered. The observer recorded the following: (1) time from the start of induction to cessation of finger tapping; (2) time from start of induction to loss of the eyelash reflex; (3) time from start of induction to jaw relaxation and insertion of the laryngeal mask airway; (4) minute volume, ventilatory frequency and tidal volume, 1 and 2 min after insertion of the laryngeal mask airway; and (5) presence or absence of adverse airway events.

Minute volumes and ventilatory frequencies were measured using a vane type spirometer (5410 Volume Monitor, Ohmeda, Louisville, USA) which gave running total averages over the previous six breaths. Tidal volumes were calculated from these values.

Laryngospasm and breath-holding, their duration and any intervention, salivation sufficient to wet a finger, coughing and excitation were noted. Excitation was graded as: no excitation; mild, slight movement of the patient; moderate, more marked movement but insufficient to interfere with induction; and severe patient movement sufficient to disrupt the induction process.

The number of patients required for the study was calculated from observations made during an earlier study using sevoflurane in nitrous oxide and oxygen[1] during which a mean ventilatory frequency of 33 (SD 6.1) bpm was noted after insertion of the laryngeal mask airway. Data for gaseous induction with halothane were less readily available, although a pilot study showed a mean ventilatory frequency of 25 (SD 6) bpm. Thus a difference in ventilatory frequency of 8 bpm could be expected with an SD of 6 bpm, leading to a standardized difference of 1.33. Using Altman's nomogram[7] for a study with a power of 0.90, 24 patients would be needed to give a significant result at the 0.05 level.

Results

After 13 patients had been enrolled, the study was stopped because the blinded observer thought that there was an unacceptably high incidence of adverse events. The randomization code was revealed and the available data examined. Of the 13 patients, six had received halothane and seven sevoflurane inductions. Mean end-expired sevoflurane and halothane concentrations after insertion of laryngeal mask airway were 3.7 (range 3.2–4.5) % and 2.0 (1.7–2.3) %, respectively.

There was a high incidence of adverse events in the halothane group, as shown in table 1. Patient No. 11 rapidly become asystolic shortly after insertion of the laryngeal mask airway. This responded to atropine, adrenaline, intubation and DC shock at 200 J twice and then 360 J. He was found subsequently to be a drug abuser and to have a cardiac conduction defect. He made a full recovery. Patient No. 3 had atrial ectopics during induction of anaesthesia which resolved spontaneously; this patient also had a crowing laryngospasm which was treated by manual ventilation. Ventilation of the lungs did not appear to have an adverse effect on the airway in this patient as laryngospasm resolved within 30 s.

Times to cessation of finger tapping and loss of eyelash reflex were comparable in both groups although times to jaw relaxation and to being settled after insertion of the laryngeal mask airway were significantly more rapid with sevoflurane (table 2).

Comparable ventilatory frequencies were seen after insertion of the laryngeal mask airway. These were associated with high minute volumes in the sevoflurane group which were maintained over the first 2 min after insertion of the laryngeal mask airway. Large tidal volumes were sustained in this group whereas they had reduced by 2 min in the

Discussion

Vital capacity induction was described originally using halothane[4 5] and seemed an acceptable technique. These studies were descriptive rather then comparative and indeed, no suitable comparator was available. Ruffle and colleagues' original work[4] used halothane in oxygen alone and Wilton and Thomas[5] developed the technique by adding nitrous oxide to the fresh gas flow so speeding the induction process. In this study, times to loss of eyelash reflex were similar to those achieved by Wilton and Thomas, and we used a similar technique, although the volatile concentration was not turned down after loss of the eyelash reflex.

With the introduction of sevoflurane, direct comparison with halothane was made.[8] Sevoflurane was found to be more acceptable, providing more rapid induction and reduced side effects. We observed similar findings in our study and found that sevoflurane was superior to the extent that it was necessary to curtail the study before completion. Although this was a small study, all patients who received halothane had either an adverse airway event or excessive excitation. The authors were surprised by the incidence of adverse events which was much higher than that in Wilton and Thomas's study.[5] The difference could be explained by deviation from the original description,[5] where halothane concentration was reduced from 4% to 3% after loss of eyelash and then to 2% after another 2 min. In our study we maintained halothane concentration at 4% because we wished to make a high concentration comparison with sevoflurane. Maintaining halothane at this level may have caused the increased side effects. The differing blood-gas solubilities of nitrous oxide and halothane (0.47 and 2.3, respectively) may also have contributed to the adverse events seen during halothane induction, as the less potent, less soluble nitrous oxide would have started to exert its effect first, producing a light plane of anaesthesia before halothane had its effect. The blood-gas solubilities of sevoflurane and nitrous oxide differ to a lesser extent (0.67 and 0.47, respectively). Of patients who experienced adverse events, the patient who had a cardiopulmonary arrest later admitted to illicit use of ephedrine as a performance enhancing drug and was found to have a mild intraventricular conduction defect.

Concentrations of the volatile agents used in this study have been used previously for vital capacity induction: 4% for halothane[4–6] and 8% for sevoflurane.[9] These were dial settings and the measured concentrations delivered were: greater than 3.5% halothane (4.4 minimum alveolar concentration (MAC) equivalents), and greater than 7.5% sevoflurane (3.8 MAC equivalents). These are not MAC equivalents, but the blood-gas solubility of sevoflurane (0.67) is so much less than that of halothane (2.3) that these were thought to be comparable techniques. A second gas effect from nitrous oxide may have had an influence on both induction times and respiratory characteristics. It would have had a more pronounced influence on the uptake of the more soluble gas halothane, perhaps leading to a dose-dependent effect on ventilation, although if this were the case one might then have expected some influence on induction times and this was not seen despite the higher MAC value used. The time to loss of eyelash reflex in the sevoflurane group was nearly 30% shorter than that in the halothane group, although this was not statistically significant. In a small study this is probably a type 2 error. The lack of adverse airway events during sevoflurane induction contributed to the earlier insertion of laryngeal mask airways in this group.

Ventilatory frequencies, and minute and tidal volumes were not noted before insertion of the laryngeal mask airway because of the difficulties in obtaining accurate results when holding a face mask. It was thought that jaw relaxation and laryngeal mask insertion represented a sufficiently definite end-point from which to obtain readings and that depth of anaesthesia would be comparable between the two groups at this stage. Ventilatory characteristics between the two groups appeared to be different. There is sustained hyperventilation associated with the use of high concentrations of sevoflurane. Before insertion of the laryngeal mask airway, ventilatory frequencies increased and in the sevoflurane group this was associated with tidal volumes which were sustained. One would expect a patient whose jaw is relaxed, and in whom it is possible to insert a laryngeal mask airway, to have some degree of respiratory depression. It is possible that jaw relaxation and depression of airway reflexes occur early with sevoflurane, enabling insertion of a laryngeal mask airway during hyperventilation either in the second stage or in the first plane of the third stage of anaesthesia. There may be some central stimulation of respiration before deepening of anaesthesia. Guedel, in his original description of the stages of anaesthesia,[10] noted respiration in the second stage as erratic. Guedel described respiration in the first plane of the third stage as full and rhythmic, the volume being increased; with uneventful first and second stages, the increase in volume may be approximately 25%. With eventful first and second stages, an increased carbon dioxide concentration causes respiratory volume to increase even further. Approximately 1 min after entering the third stage, respiration adjusts to moderate hyperventilation.[10] These stages were described during induction with ether with patients breathing normally and the hyperventilation described was attributed to an increase in arterial carbon dioxide tension. During vital capacity induction, greater accumulation of carbon dioxide might be expected, leading perhaps to a more pronounced effect. Tachypnoea but not hyperventilation did not occur during halothane inductions. During sevoflurane induction, respiration seemed to be regular and associated with hyperventilation. The respiratory pattern could represent either the second stage of anaesthesia in a simpler form, unaffected by the complications of airway irritation and patient movement, or the first plane of the third stage of anaesthesia. Whatever stage was present, the laryngeal mask airways were inserted at an earlier stage of anaesthesia in the sevoflurane group. The end-tidal volatile concentrations at insertion of the laryngeal mask airway would seem to support this, with the mean end-tidal sevoflurane concentration being 3.7% or 1.85 MAC and the mean end-tidal halothane 2.0% or 2.5 MAC.

The use of sevoflurane in a vital capacity induction technique was associated with sustained minute volumes, a phenomena which may be responsible in part for the rapid deepening of anaesthesia in sevoflurane vital capacity induction. Sevoflurane would appear to be superior to halothane for adult vital capacity induction when the initial halothane concentration is maintained throughout the induction period. If adult gaseous induction with halothane is to be used, then perhaps the halothane concentration should be reduced after initial loss of consciousness as in Wilton and Thomas's original description.[5]

Laryngeal mask airway and uncuffed tracheal tubes are equally effective for low flow or closed system anaesthesia in children

D. FRÖHLICH, B. SCHWALL, W. FUNK AND J. HOBBHAHN

Summary

Low flow and closed system anaesthesia have considerable advantages in economy, limited atmospheric pollution, and maintenance of humidification and temperature. To benefit from these techniques leakage from the breathing system should be as low as possible. The sealing of the airway is crucial to ensure this. Therefore, we have investigated in 30 children, aged 2–6 yr, the effectiveness of the laryngeal mask airway (LMA) and the uncuffed tracheal tube (TT) for closed system paediatric anaesthesia, during positive pressure ventilation, in a prospective, randomized study. Ventilation was adequate in all cases with both devices. Loss of gas from the breathing system was less than 100 ml min^{-1} in 13 (87%) patients in the LMA and in 12 (80%) patients in the TT group, with a maximum of approximately 700 ml min^{-1} in the TT and approximately 350 ml min^{-1} in the LMA group. We conclude that the airway sealing with both devices was tight enough to perform low flow or closed system anaesthesia in paediatric patients aged 2–6 yr. (*Br. J. Anaesth.* 1997; **79**: 289–292).

Key words
Anaesthesia, paediatric. Equipment, anaesthesia machines. Equipment, masks anaesthesia. Ventilation, positive end-expiratory pressure. Intubation tracheal. Children.

The uncuffed tracheal tube (TT) is the established standard in paediatric airway management during anaesthesia. Although the laryngeal mask airway (LMA) does not provide a watertight seal, it has been used safely for positive pressure ventilation in both children and adults. Airway management is adequate in approximately 90% of infants and children.[1–5] The incidence of coughing, with and without desaturation, wheezing and hoarseness was significantly lower in the postoperative period using the LMA compared with the TT.[6] The use of closed circle systems has considerable advantages over semi-closed or semi-open systems in economy, limited atmospheric pollution, and maintenance of humidification and temperature.[7 8] These latter advantages are especially important in paediatric anaesthesia.

To assess the effectiveness of the LMA or uncuffed TT in anaesthesia techniques with reduced fresh gas flow rate, it is necessary to measure gas loss during positive pressure ventilation (PPV). Data derived from adults may not be applicable to children, as paediatric adaptations of both the LMA and TT differ considerably from the adult design.

We have investigated the efficacy of both airway devices with respect to respiratory variables, capnography and gas loss from a closed system during PPV, in a prospective, randomized study.

Patients and methods

With the approval of our institutional review board and written informed consent from parents, we studied 30 healthy children undergoing short elective surgical or diagnostic procedures with a predicted laryngeal mask airway size 2 (table 1). The study was prospective and randomized for insertion of a tracheal tube (TT) or a laryngeal mask airway (LMA). Randomization was performed using a random number generator. Even or odd numbers were assigned to either of the airway devices. Twenty of 30 children received laser treatment for facial portwine stains and 10 underwent diagnostic procedures of the eyes.

ANAESTHESIA

The children were allowed solids until 8 h and clear fluids until 3 h before anaesthesia. Midazolam 500 µg kg^{-1} was administered orally as premedication, 60 min before induction of anaesthesia. Anaesthesia was induced with propofol 2–3 mg kg^{-1} until disappearance of the eyelash reflex, followed by atracurium 0.4 mg kg^{-1} for neuromuscular block.[9] After ventilation of the lungs by mask with pure oxygen for 3 min, a TT or LMA was inserted. A size 2 LMA was used, as recommended by the manufacturers for children weighing 6.5–25 kg. The cuff of the LMA was inflated stepwise until the audible leak decreased. Cuff pressure was monitored continuously. To provide standardization a formula was used to calculate the size of the uncuffed TT

age-dependently, although a clinically based approach might result in a better fit of the tracheal tubes. The formula was as follows: internal diameter (id) = (16 + age (yr)) / 4 (mm). The wall thickness of the TT ranged from 0.76 to 0.91 mm.

After satisfactory ventilation with several manual breaths, the airway device was connected to the anaesthesia machine. Ventilation was continued as PPV. Tidal volume was set at 10 ml kg^{-1} and ventilatory frequency was adjusted based on end-tidal carbon dioxide readings. Anaesthesia was maintained with propofol 10 mg kg^{-1} h^{-1} and oxygen–air with an $F\text{I}_{\text{O}_2}$ of 0.4 until the end of the diagnostic or therapeutic procedure. All children were supine and were monitored during anaesthesia with non-invasive arterial pressure, ECG, pulse oximeter and an end-tidal gas monitor integrated into the anaesthesia ventilator. At the end of the surgical or diagnostic procedure, ventilation was switched from mandatory to assisted ventilation until spontaneous breathing recurred. Neuromuscular block was not antagonized. End-tidal carbon dioxide values were maintained at less than 5.3 kPa. The airway devices were left in place until patients opened their eyes.

ANAESTHESIA EQUIPMENT

The anaesthesia machine was a valveless high flow (70 litre min^{-1}) closed system device (PhysioFlex, Physio, Haarlem, The Netherlands). The core of this ventilator consists of up to four membrane chambers coupled in parallel (fig. 1).

When the patient is connected to the anaesthesia machine and it is switched to mechanical PPV, the inspiratory valve (valve 1 in fig. 1) opens and pressurized driving air enters the external part of the membrane chambers. After the preset tidal volume is reached, the inspiratory valve (1 in fig. 1) is closed and plateau pressure remains constant until expiration is started. Then the expiratory valve (3 in fig. 1) of the external part of the system is opened and pressure in the system returns to environmental pressure. The membranes move back towards the original position. The membranes are equipped with sensors so that total volume displacement of the system during ventilation can be measured. $F\text{I}_{\text{O}_2}$ and the volume inside the closed system are regulated by a computer using PID (proportional integrating and differentiating) regulating algorithms. Regulation of $F\text{I}_{\text{O}_2}$ is based on oxygen loss of the closed system and has the highest priority. The volume is regulated depending on the membrane position before and after each ventilation cycle. The computer maintains $F\text{I}_{\text{O}_2}$ and volume constant with 5-ml pulses of oxygen, or of the selected carrier gas (air or nitrous oxide), respectively. Leakage of the system corresponds to the carrier gas flow necessary to maintain the volume constant in the system. In the case of the system being completely airtight, there would be no carrier gas flow, as volume loss, oxygen uptake of the patient, is balanced by oxygen flow to the system and no additional carrier gas has to be added. This assumption that carrier gas flow equals leakage has limitations. First, it applies only to air as the carrier gas, as uptake of nitrous oxide or halogenated volatile anaesthetics by the patient would lead to volume loss and therefore to overestimation of leakage. Second, the fact that the lost gas contains oxygen and not only nitrogen leads to systematic

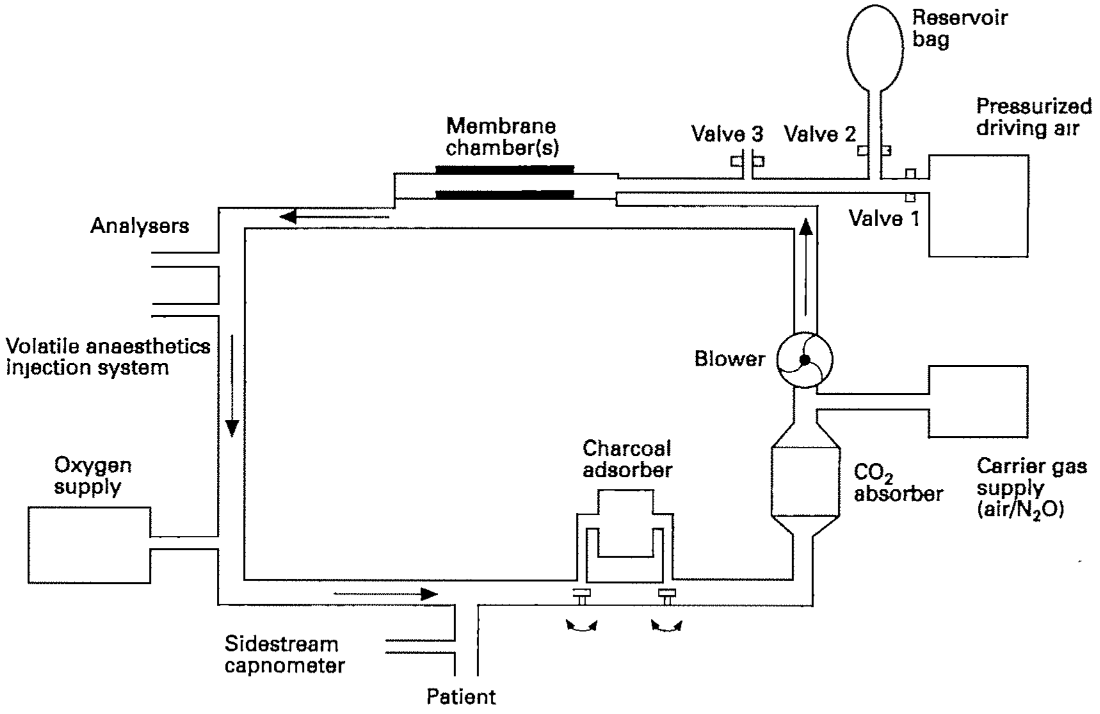

Figure 1 Schematic diagram of the valveless high flow (70 litre min^{-1}) closed system device (PhysioFlex) used in this study to assess leakage of the TT or LMA. The membranes of the chambers form an airtight barrier between driving pressurized air and the closed system. Valves are numbered 1–3: inspiratory valve or driving air inlet (1), valve to the reservoir bag (2) and expiratory valve or driving air outlet (3).

underestimation of the leakage of approximately 20%. This underestimation has been corrected in the values given in the summary.

The data presented are the mean values over 10 consecutive minutes after the anaesthesia device reached its steady state. This was assumed when the preset oxygen concentration of 35% was maintained stable for 5 min. Steady state was reached at 10–12 min after induction. Maximum errors for the oxygen and carrier gas feedback controls are 5%. The accuracy of the system for tidal volume is ±5% or 5 ml, for respiratory pressures ±10% or 0.27 kPa, and for gas flow rates ±5% or 10 ml min^{-1}, according to the manufacturer's data.

STATISTICAL ANALYSIS

All data, with the exception of data on gas flow rates, are presented as mean (SD). Taking account of the skewness of distributions, gas flow rates are given as median (range). To evaluate differences between groups the Student's *t* test was used for continuous variables with a normal distribution, whereas for continuous variables without a normal distribution the Mann–Whitney *U* test was used. Normality of distribution was tested by the Lilliefors test.[10] Fisher's exact test was used to compare nominal data differences. A significance level of $P \leq 0.05$ was considered significant. The sample size was calculated to have a power of 90% to detect a 10% difference in carrier gas flow.

Results

The two groups did not differ appreciably in age, weight and sex distribution (table 1). Ventilation was adequate in all cases; vital signs were within normal ranges during and after anaesthesia. Ventilatory frequencies, tidal volumes, peak pressures, plateau pressures and mean pressures were comparable in both groups (table 2).

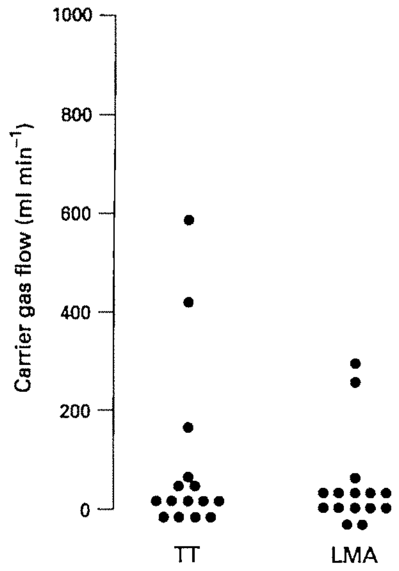

Figure 2 Carrier gas flow rates necessary to maintain the volume of the closed system stable during positive pressure ventilation in the TT and LMA groups. Carrier gas flow rate is fresh gas flow rate minus oxygen flow rate.

During emergence, we found no differences in complications such as laryngospasm, bronchospasm or hypersalivation. The incidence of coughing and breath-holding was higher in the TT group. The incidence of coughing was 53% (eight patients) with the TT and 13% (two patients) with the LMA ($P=0.05$). Breath-holding occurred in eight children (53%) in the TT group and in one child (7%) in the LMA group ($P=0.014$).

Fresh gas flow rate, oxygen uptake and air expenditure necessary to maintain the volume of the closed system stable are presented in figure 2 and table 3. Carrier gas flow was less than 100 ml min^{-1} in 13 (87%) patients in the LMA group and in 12 (80%) patients in the TT group.

End-tidal carbon dioxide was measured at the end of the respective device. In both groups a capnogram

was recorded. Curves and data for end-tidal carbon dioxide were comparable in both groups.

Discussion

The desired tidal volume was delivered effectively in both groups. This is in accordance with studies in adults comparing an LMA with a cuffed TT.[11] We found no significant differences between the uncuffed TT and LMA with respect to the amount of oxygen or air necessary to maintain the volume of the closed system constant. Carrier gas flow was less than 100 ml min^{-1} in 13 (87%) patients in the LMA group and in 12 (80%) patients in the TT group (fig. 2). The maximum values of carrier gas loss were 584 ml min^{-1} (TT group) and 293 ml min^{-1} (LMA group). This low leakage in both groups would allow low flow or closed system anaesthesia to be undertaken appropriately. Devitt and co-workers investigated leakage of the LMA in adult patients during IPPV.[11] Leakage was assessed as the difference between expiratory and inspiratory volume. The leak increased depending on the applied airway pressure and they concluded that ventilation, using the LMA, is adequate if airway resistance and pulmonary compliance are normal. Gursoy, Algren and Skjonsby[12] investigated the amount of air leakage around LMA size 2 during IPPV with regard to gastric distension. The authors measured the circumference of the upper abdomen and found no significant difference between the TT and LMA. Neuromuscular blocking agents were used by these authors[12] only in the TT group and this may have influenced the comparison.

We observed a normal capnogram in both groups and mean end-tidal carbon dioxide was similar in both groups. Thus capnometry and capnography provide the necessary information for the anaesthetist on ventilatory status, correct placement of the airway device and accidental disconnection.

Chhibber and colleagues[13 14] studied Pa_{CO_2} and end-tidal carbon dioxide during IPPV via a TT or LMA in paediatric patients aged 1 month to 16 yr. They found that capnometric data were accurate and comparable with those recorded via a TT.

In accordance with the findings of Ferrari and Goudsouzian,[6] we found that the incidence of coughing and breath-holding was significantly lower in the LMA group. Nevertheless, the number of children studied was small and we cannot draw any conclusions on complications such as bronchospasm or laryngospasm. However, our findings demonstrate some of the advantages of the LMA in comparison with tracheal intubation. On the other hand, laryngeal masks do not always position well, particularly in small infants requiring a size 1 LMA.[2 5] Although the youngest children in this study were 2 yr of age, mean age was 3–4 yr. Therefore, the findings of this study may not reflect the situation in small infants.

Caudal tramadol for postoperative analgesia in paediatric hypospadias surgery

D. P. PROSSER, A. DAVIS, P. D. BOOKER AND A. MURRAY

Summary

Ninety boys, aged 13–53 months, undergoing repair of hypospadias, were allocated randomly to receive 0.8 ml kg^{-1} of one of three solutions into the caudal extradural space: group B received bupivacaine 2 mg kg^{-1}, group T received tramadol 2 mg kg^{-1} in 0.9% saline and group BT a mixture of both. Postoperative pain was assessed hourly for 12 h after injection using a modified TPPPS pain score and additional analgesia was administered to those children whose pain scores were >3/10. Nine patients (30%) in group T required additional analgesia within 1 h of surgery compared with only two (6.7%) and three (10%) patients in groups B and BT, respectively (P=0.04). Mean duration before additional analgesia was required in the remaining patients was 9.3 (SD 3.0) h in group B, 10.7 (2.2) h in group T and 10.5 (2.0) h in group BT (P>0.20). There were no significant differences between the groups in mean ventilatory frequency, sedation scores, incidence of emesis, facial flushing or pruritus. We conclude that caudal tramadol had a slow onset of action and that the addition of tramadol to bupivacaine, when both drugs were administered caudally, did not significantly prolong the duration of action of bupivacaine. (*Br. J. Anaesth.* 1997; **79**: 293–296).

Key words

Analgesia, paediatric. Analgesic techniques, extradural. Anaesthetics local, bupivacaine. Analgesics opioid, tramadol. Surgery, urological. Pain, postoperative.

Although administration of bupivacaine into the caudal extradural space has been our standard method of providing postoperative analgesia for hypospadias repair, a single injection may have only a relatively short duration of action.[1–4] Placement of a catheter into the extradural space either at the caudal or lumbar region adds to the risk of infection and tends to prevent early mobilization.[5] Attempts to overcome these problems by combining local anaesthetic agents with other drugs such as adrenaline,[1,2] clonidine,[2] ketamine[2,3] or various opioids[4,6–10] have met with varied degrees of success. Problems with emesis, sedation, nausea, itching or respiratory depression have limited their usefulness.[11]

Tramadol, a synthetic 4-phenyl-piperidine analogue of codeine, has been available in the UK since 1994, although is it licensed only for use in children aged >12 yr. Tramadol is a racemic mixture of two enantiomers, (+)-tramadol and (−)-tramadol. The (+)-enantiomer has a moderate affinity for the opioid μ receptor, greater than that of the (−)-enantiomer.[12] In addition, the (+)-enantiomer inhibits serotonin uptake and the (−)-enantiomer is a potent noradrenaline inhibitor, complementary properties which result in a synergistic antinociceptive interaction between the two enantiomers.[12] The result is an opioid with a striking lack of respiratory depressant effect despite an analgesic potency approximately equal to that of pethidine.[13–15] Furthermore, animal work has suggested that tramadol may have a selective spinal action.[16,17] Tramadol has been shown to provide effective, long lasting analgesia after extradural administration in both adults[18,19] and children[20] and prolongs the duration of action of mepivacaine used for brachial plexus block.[21]

We wished to determine if caudal tramadol could provide effective, long lasting analgesia and if the addition of tramadol to bupivacaine would significantly extend the duration of analgesia produced by bupivacaine alone.

Patients and methods

After obtaining local Ethics Committee approval and written, informed parental consent, we studied 90 healthy boys, ASA I–II, aged 13–53 months, who required surgical repair of hypospadias. Those children receiving medication likely to have interactions with opioids or cause sedation, those in whom caudal analgesia was contraindicated and those being discharged on the day of surgery were excluded.

No premedication was used. After cannulation of a vein, anaesthesia was induced with thiopentone 5 mg kg^{-1} and tracheal intubation was facilitated

Table 1 Modified TPPPS pain score. The same variables validated in the original score were used, but scored so that the maximum score was 10, rather than 7 as in the original. The five pain behaviour items were scored hourly during a 5-min observation period. Each variable was defined as in the original TPPPS score[22]

Variable	Score 0	Score 1	Score 2
Verbal complaint/cry	None	Once only	>Once
Groan/moan/grunt	None	Once only	>Once
Facial expression	Neutral	One grimace	Grimace>once
Restless motor behaviour	None	One episode only	>One episode
Rub/touch painful area	None	Once only	>Once

using atracurium 0.5 mg kg^{-1}. Anaesthesia was maintained with 1–1.5% isoflurane and 70% nitrous oxide in oxygen. Patients were allocated randomly (sealed envelope, random number table) to receive one of three solutions, diluted with 0.9% saline as necessary, so that the volume injected into the caudal extradural space was 0.8 ml kg^{-1}. Group B received bupivacaine 2 mg kg^{-1}, group T tramadol 2 mg kg^{-1} and group BT bupivacaine 2 mg kg^{-1} together with tramadol 2 mg kg^{-1}. No other peroperative analgesia was given. Anaesthesia was discontinued when the wound dressing had been applied; residual neuromuscular block was antagonized with neostigmine 50 μg kg^{-1}, given together with atropine 20 μg kg^{-1}, and the patient's trachea was extubated before transfer to the recovery area.

When the patient was awake in the recovery area, heart rate, arterial pressure, peripheral oxygen saturation, ventilatory frequency and pain score were recorded before discharge to the surgical ward. On arrival in the surgical ward a research nurse, who was unaware of the nature of the caudal injection, performed hourly observations until 12 h after the caudal injection. A TPPPS pain score,[22] modified to give a maximum score of 10 (table 1), was used to assess pain over a 5-min period every hour. Ventilatory frequency and a four-point sedation score (0=eyes open spontaneously; 1=eyes open to speech; 2=eyes open when shaken; 3=unrousable)[23] were also measured hourly. A pain score >3/10 resulted in administration of either i.v. morphine 100 μg kg^{-1} or oral paracetamol 20 mg kg^{-1}, as deemed appropriate. Episodes of nausea, vomiting, facial flushing or pruritus were noted if they occurred.

Mean age, weight, pain and sedation scores, and time to additional analgesia in each group were compared with each other using one-way analysis of variance (ANOVA) with *post hoc* comparisons using the Bonferroni multiple range test. The Pearson chi-square test with Fisher's exact test were used to compare the incidence of use of postoperative urinary catheters and complication rates in the three groups.

Results

Median age and weight of the patients were similar in all three groups (table 2). There were significantly more patients requiring additional analgesia in the recovery room immediately after surgery in group T compared with the two other groups (P=0.04) (table 2). Mean hourly pain scores in the three groups who left the recovery room without first requiring additional analgesia were similar from 4 h after injection and thereafter. However, the mean score in group T was significantly higher than that in groups B and BT 3 h after injection (fig. 1).

Mean duration of analgesia for those patients who left the recovery area without first requiring additional analgesia did not differ significantly between groups (table 3).

There were no significant differences between the three groups in mean hourly sedation scores or ventilatory frequencies. Although the incidence of

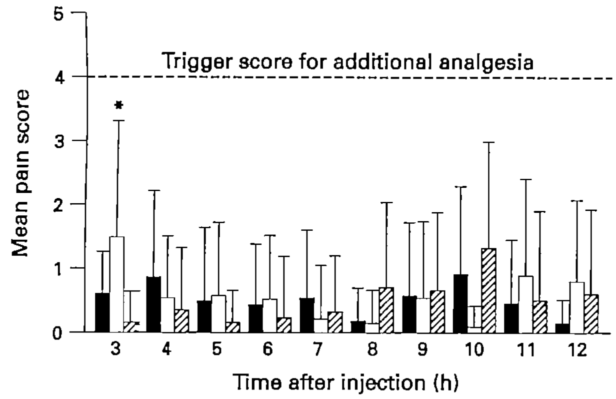

Figure 1 Mean hourly pain scores in the three groups of patients from 3 to 12 h after caudal injection. Group B (■) received bupivacaine 2 mg kg^{-1}, group T (□) tramadol 2 mg kg^{-1} and group BT (▨) bupivacaine 2 mg kg^{-1} together with tramadol 2 mg kg^{-1}. All drugs were injected into the caudal extradural space and diluted in 0.9% saline as necessary to a total volume of 0.8 ml kg^{-1}. Data for patients requiring morphine in the recovery room have been excluded *$P<0.05$.

emesis was higher in both tramadol groups (T and BT) than in the bupivacaine group, the differences were not statistically significant (table 4). The incidence of pruritus and numbness was low in all groups. Surprisingly, the incidence of noticeable facial or more generalized flushing, or both, exceeded 30% in all three groups, although it was not obviously distressing to the individuals affected.

Discussion

We have found that tramadol, when injected into the caudal extradural space, produced useful analgesia for up to 12 h after hypospadias surgery. However, if the period of time between performing the caudal injection and recovery of the child from anaesthesia was <2 h, the incidence of immediate pain (requiring rescue analgesia) was high (30%), demonstrating a slow onset of action of caudal tramadol. However, if the operation was longer, then caudal tramadol produced good quality analgesia for an average of 10.7 (2.2) h. Although adding tramadol to our usual dose of caudal bupivacaine slightly prolonged the mean duration of action of bupivacaine, the difference was not statistically significant.

Studies in rodents[16 17] suggested that tramadol has a selective spinal action similar to that of other opioids. This view was supported indirectly by one clinical study in adults which found much lower serum concentrations of tramadol after extradural injection[24] than were described subsequently after i.v. injection.[25] It is not clear if the delay in onset of tramadol analgesia observed in our study was caused by slow absorption across the dura or slow uptake of tramadol from the extradural space into the systemic circulation. Tramadol has a lipid solubility comparable with that of morphine, which may account for its slow onset of action. However, most clinical studies that have examined the effects of extradural tramadol[18–20 26] have used dose regimens that are broadly similar to those used i.v.[13–15 27–30] Furthermore, preliminary results from our on-going pharmacokinetic study, which have shown that mean serum concentrations 2–8 h after either i.v. or caudal injections of tramadol are not significantly different, tend to support the view that systemic absorption of extradural tramadol may be necessary for its action.

Although a previous study demonstrated that tramadol, when added to mepivacaine, significantly prolonged the duration of brachial plexus block,[21] we could not demonstrate that the addition of tramadol prolonged significantly the action of caudal bupivacaine. However, the mean duration of action of caudal bupivacaine in our study appeared somewhat longer than that found in previous studies.[2 9 31 32] Differences in the operations performed, method of pain scoring, bupivacaine dose and volume, and calculation of analgesia time probably account for this discrepancy.

Eleven or 12 children in each group (37–40%) required an indwelling urinary catheter for some days after surgery; there was no significant difference in this incidence between groups ($P=0.61$) (table 2). Often the first indication for additional analgesia in these children was related to acute attacks of "bladder spasm". These short-lasting periods of intense discomfort seem peculiar to children requiring an indwelling urinary catheter after hypospadias surgery, for surgical reasons, and it is possible that the duration of tramadol analgesia may be longer in patients not subject to such problems. The duration of analgesic action was taken as the time from caudal injection to first administration of supplementary analgesia. If by 12 h no additional analgesia had been required, we assumed for the sake of comparison that the duration of analgesia was 12 h, although it is possible that useful analgesia may have continued for longer. However, logistical problems dictated that further observations were impracticable and after the 12 h observations were complete, there was a tendency for prophylactic paracetamol analgesia to be given by the ward nurses to any patient who was still awake. All patients were managed successfully with paracetamol alone after this time.

In conclusion, we have shown that when a single caudal injection of tramadol was used in young children it provided analgesia for up to 12 h without a significant incidence of side effects. However, the slow onset time of caudal tramadol necessitated that it was given with a local anaesthetic agent such as bupivacaine to ensure good analgesia on recovery from anaesthesia. As an adjunct to bupivacaine, tramadol may prove more useful in young children and infants than other opioids because of its lack of respiratory depressant effects. However, this property may imply that there is little advantage in injecting tramadol into the extradural space and that i.v. administration may be equally efficacious. Further dose-ranging and pharmacokinetic studies in young children are required before the optimum route of administration of tramadol can be determined.

Comparison of single, end-holed and multi-orifice extradural catheters when used for continuous infusion of local anaesthetic during labour

M. A. S. DICKSON, C. MOORES AND J. H. MCCLURE

Summary

Single, end-holed and multi-orifice extradural catheters were compared in terms of efficacy and complications when used for infusion of 0.1% bupivacaine during labour. In this study of 364 patients there was no difference in unilateral block after an initial bolus dose (18 (11.5%) for single, end-holed and 16 (10.9%) for multi-orifice catheters). Unilateral block recurred with seven (4.0%) single, end-holed and with eight (4.8%) multi-orifice catheters. Unilateral blocks, arising for the first time during infusion of local anaesthetic, occurred significantly more frequently when single, end-holed catheters were used (29 (16.4%)) compared with multi-orifice catheters (14 (8.4%)) ($P<0.05$). (*Br. J. Anaesth.* 1997; **79**: 297–300).

Key words
Equipment, catheters extradural. Anaesthesia, obstetric.

There are two types of extradural catheter currently available in the UK: the single or end-holed and the multi-orifice (lateral eyed) catheter. Comparisons have been made in relation to complications associated with their use.[1–3] Single, end-holed catheters avoid the risk of partial subarachnoid or vascular placement, a recognized problem with multi-orifice catheters.[4] Multi-orifice catheters, however, are considered to allow more even spread of local anaesthetic within the extradural space.[2 3] All studies to date have considered only the quality of analgesia and complications after bolus injection of local anaesthetic. This study was undertaken to compare the efficacy and incidence of complications during continuous extradural infusion of local anaesthetic.

Patients and methods

The study was approved by the local Ethics Committee and took place over a 2-yr period. Verbal informed consent was obtained from all participants. As we were studying two types of catheter in routine use in the unit, and as the observations being made were standard practice, the Ethics Committee considered that written consent was not required. Mothers who requested extradural analgesia for labour pain were included in the study if they were in early labour or not expected to deliver within 3 h. Consultant and trainee anaesthetists working in the Simpson Memorial Maternity Pavilion, Royal Infirmary of Edinburgh, participated by including suitable patients, using a standard extradural technique and recording data during extradural infusion.

Patients were allocated randomly using computer generated random numbers and a sealed envelope technique to receive either a single, end-holed or a multi-orifice catheter. Using a 16-gauge Portex disposable Tuohy needle, the extradural space was identified by loss of resistance to saline. A volume not exceeding 4 ml of normal saline was injected into the extradural space. The catheter was passed in a cranial direction leaving 2–4 cm of single, end-holed or 3–5 cm of multi-orifice catheter within the extradural space. These lengths were chosen on the basis of current practice within the unit. It was intended that the proximal orifices of the multi-orifice catheters would lie in a similar position within the extradural space as the orifice of the single, end-holed catheters. After negative aspiration of the catheter a test dose of 2% lignocaine 4 ml was given. A record was made of dural puncture, cerebrospinal fluid aspiration from the catheter, paraesthesia on catheter insertion, whether or not the meniscus within the catheter decreased easily, blood in the catheter or symptoms of systemic toxicity after the test dose. The extradural block was established with 0.25% or 0.5% bupivacaine 8 ml, as considered necessary on clinical grounds by the anaesthetist at that time. After 20 min, block height was assessed on both sides of the abdomen or upper legs using ethyl chloride spray and the quality of analgesia was recorded as good, moderate or poor. A standard continuous infusion of 0.1% bupivacaine was commenced at 20 ml h^{-1}. Additional top-up doses of 0.25% bupivacaine 8 ml were prescribed, to be given by the attending midwife. Occurrence of unilateral block, missed segment and quality of analgesia were assessed by the midwife using a three-point pain score. The anaesthetist was called on the first occasion that a unilateral block was demonstrated

Catheter type	Dural puncture	CSF on aspiration	Paraesthesia on insertion	Meniscus decreases easily	Blood in catheter	Toxic symptoms on test dose
Single, end-holed	1 (0.5%)	0	44 (23.0%)	140 (88.6%)	8 (4.3%)**	3 (1.6%)
Multiorifice	1 (0.5%)	0	34 (19.4%)	149 (85.6%)	21 (12.1%)**	3 (1.7%)
No record	2	0	0	17	8	0

and the extent of block was assessed by ethyl chloride spray. Any treatment required was recorded and the block was reassessed by the anaesthetist 20 min later.

Data were analysed statistically using the chi-square method with Yates' correction. $P<0.05$ was considered significant.

Results

We collected and analysed 364 records. There were two dural punctures with the Tuohy needle but no catheter was identified as being within the subarachnoid space. Transient paraesthesia on insertion of the catheter was experienced by 44 patients in the single, end-holed group and by 34 patients in the multi-orifice group (table 1). Bupivacaine 0.25% was used to produce block in 54.1% of participants in the multi-orifice group and in 51.4% of participants in the single, end-holed group. Bupivacaine 0.5% was used to produce block in 45.9% of participants in the multi-orifice group and in 48.6% of participants in the single, end-holed group (ns; chi-square test). The meniscus of fluid within the catheter was seen to decrease easily when the catheter was raised above the point of insertion in similar numbers in each group (140 *vs* 149) (table 1). Six patients experienced symptoms of systemic toxicity after the test dose of local anaesthetic. In two cases the catheter was resited (both single, end-holed catheters) and one multi-orifice catheter was withdrawn by 1 cm. In the three other cases there was no record of the action taken. The multi-orifice catheter group had an increased incidence of blood tinged fluid in the catheter on insertion (21 *vs* 8) ($P<0.01$) (table 1).

Quality of analgesia was recorded as good with no evidence of unilateral block or missed segments in 140 (86%) patients in the single, end-holed group and in 132 (86%) patients in the multi-orifice group (table 2).

Table 2 Adequacy of analgesia after initial establishment of block

	Analgesia after block produced		
Catheter type	Good	Moderate	Poor
Single, end-holed	140	18	5
Multi-orifice	132	17	4

There was no significant difference between the two groups (18 *vs* 16) in the incidence of unilateral block at the 20-min assessment (table 3). After satisfactory bilateral block had developed with an additional local anaesthetic bolus, a similar number of patients (seven of 18 in the single, end-holed group and eight of 16 in the multi-orifice group) subsequently developed recurrence of the unilateral block (ns) (table 3). The incidence of a new unilateral block developing during infusion of the local anaesthetic was 29 (16.4%) in the single, end-holed group and 14 (8.4%) in the multi-orifice group ($P<0.05$) (table 3).

Intervention required for treatment of unilateral block was minimal in that only two catheters were resited. Withdrawal of the catheter, top-up of local anaesthetic or local anaesthetic with fentanyl, posture or a combination of these sufficed for all others.

Discussion

Continuous infusion of dilute local anaesthetic solution into the extradural space is now a commonly used technique for analgesia in labour.[5] There has been a need for clinical investigation into the performance characteristics of the two extradural catheter types when used for a continuous infusion technique. Previous studies comparing the two catheter types after bolus administration have produced different results.[1–3] In this study the distribution of sensory block obtained with the two types of catheter in common use was examined during infusion of dilute local anaesthetic.

Single, end-holed catheters have been advocated by some as being inherently safer as partial subarachnoid or vascular placement is avoided. In a radiological study, Beck and colleagues identified a frequency of 11.5% partial vascular and 0.9% partial subarachnoid placement of multi-orifice catheters and recommended that these catheters should not be used.[4] Ward and colleagues reported a death associated with the use of a double orifice catheter caused by partial subarachnoid placement.[6] Although this

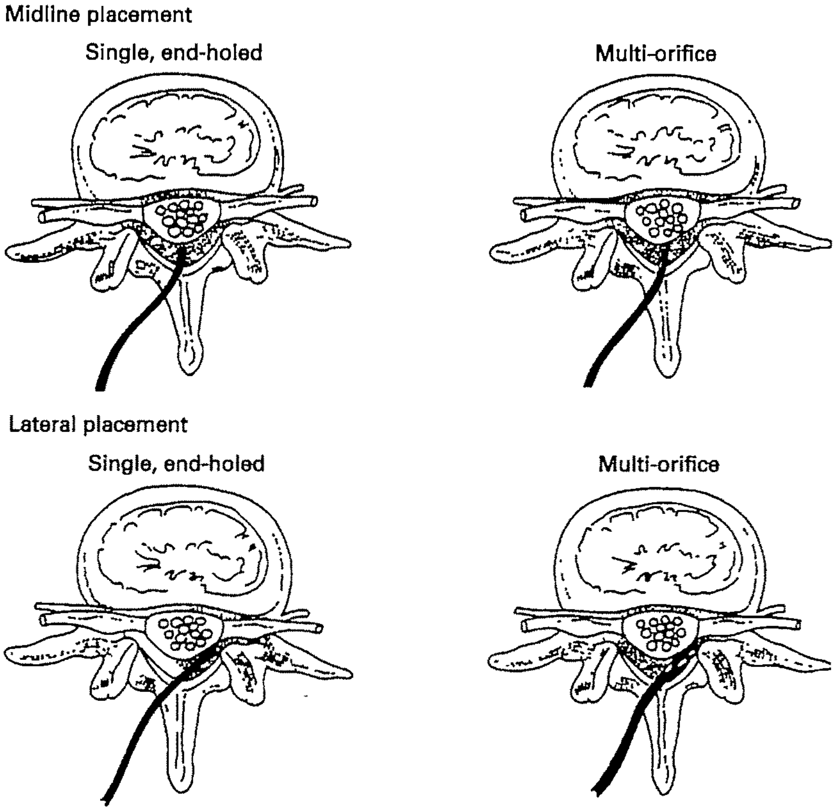

Figure 1 Spread of local anaesthetic in the extradural space administered by low pressure infusion through single, end-holed and multi-orifice catheters placed in the midline or laterally. Spread of local anaesthetic is shown as shading. Top: midline placement of either catheter type results in bilateral spread of local anaesthetic in the extradural space. Bottom: when placed laterally, unilateral block develops with single, end-holed catheters, but bilateral spread may occur with multi-orifice catheters as local anaesthetic preferentially emits from the proximal, centrally positioned orifice during low pressure infusion.

type of catheter is not identical to the multi-orifice catheter, the potential for such misplacement still exists. It has been demonstrated *in vitro* that when multi-orifice catheters are used for bolus administration, the distribution of local anaesthetic is dependent on the rate and pressure of the injection with most of the solution emitting from the proximal orifice when a low injection rate and pressure are used.[6,7] However, some of the potentially serious shortcomings of the multi-orifice catheter have been viewed by some workers as positive benefits.[8] With unidentified partial subarachnoid, intravascular placement or late catheter migration, the volume of local anaesthetic deposited outside the extradural space may be reduced. With end-holed catheters late catheter migration may result in a considerably larger volume of local anaesthetic entering the subarachnoid space.

In this study there was no accidental subarachnoid or intravascular catheter placement of local anaesthetic administration during the initial bolus dose or infusion in either group, but six patients had a reaction to the test dose. There was no difference between the two groups in the incidence of dural puncture using the Tuohy needle, the incidence of low resistance, as assessed by the meniscus decreasing easily, or paraesthesia, on catheter insertion.

Blood was found in the catheter significantly more frequently in the multi-orifice group. These findings are similar to those of previous studies.[1,2] This increased incidence in association with multi-orifice catheters is considered to be a result of a higher detection rate of vascular trauma rather than an increased incidence of vascular placement.[1] Collier and Gatt reported one case of intravascular placement with negative aspiration of blood from a single, end-holed catheter, perhaps because the end hole was against the vessel wall.[3] Satisfactory analgesia during labour requires bilateral spread of local anaesthetic within the extradural space. After bolus administration Michael, Richmond and Birks demonstrated that at 30 min there was more even distribution of local anaesthetic using multi-orifice catheters as evidenced by a significantly reduced incidence of unilateral block or missed segments compared with single, end-holed catheters.[2] Collier and Gatt found an unacceptably high incidence of unsatisfactory block with single, end-holed catheters (32% in the single, end-holed group compared with 12% in the lateral eye catheters).[3] In contrast, after a bolus dose of local anaesthetic, Morrison and Buchan were unable to detect any difference in incidence of unilateral block comparing the two catheter types at initial assessment.[1]

Interestingly, a recent study using a 10-ml bolus of radio-opaque contrast medium demonstrated more even distribution of dye within the extradural space with single, end-holed catheters compared with multi-orifice catheters.[9]

Our clinical study supports the findings of Morrison and Buchan[1] in that there was no difference in the incidence of unilateral block after bolus administration. Seven patients in the single, end-holed group and eight patients in the multi-orifice group had recurrence of unilateral block. During infusion of the local anaesthetic, 29 of 163 (16.4%) patients in the single, end-holed group and 14 of 153 (13%) patients in the multi-orifice group developed a new unilateral block. The higher incidence of unilateral blocks occurring for the first time in the single, end-holed catheter group during extradural local anaesthetic infusion was significant.

Midline placement of both types of catheter is presumed to result in bilateral spread of local anaesthetic (fig. 1, top). This would also be the case with lateral placement of a multi-orifice catheter inserted in the midline, as most of the volume of local anaesthetic infused at a low pressure takes the path of least resistance through the proximal orifice which is placed centrally. However, with lateral placement the end hole of a single, end-holed catheter deviates from the midline and distribution of an infusion of local anaesthetic is unilateral (fig. 1, bottom). It is our suggestion that this unilateral distribution may be overcome by bolus administration of a larger volume producing spread to the opposite side. As an initial bolus dose of local anaesthetic (0.25% or 0.5% bupivacaine 8 ml) was used to produce extradural block, lateral placement of a single, end-holed catheter may not be immediately apparent.

The length of catheter in the extradural space may influence spread of local anaesthetic. In this study, single, end-holed catheters were inserted for 2–4 cm into the space and multi-orifice catheters 3–5 cm, which reflected the current clinical practice in the maternity hospital. Michael, Richmond and Birks[2] placed 1.5 cm of single, end-holed and 2.5 cm of lateral eyed catheters into the extradural space. Collier and Gatt[3] placed 3–4 cm of either catheter type in the space and suggested that this may be too great for a single, end-holed catheter. Morrison and Buchan[1] inserted 3 cm or less of each catheter type in the space without observing any difference in the incidence of unilateral block. Beilin, Bernstein and Zucker-Pinchoff showed that 5 cm was optimal for a multi-orifice catheter.[10]

The advantage of more even spread of a local anaesthetic should be balanced against the danger of multi-compartment block. No multi-compartment blocks were detected in our study, or in other controlled studies comparing the two catheter types. A newer multi-orifice catheter with the holes distributed more closely together may reduce the risk of multi-compartment block while providing more even distribution of local anaesthetic during low pressure infusion.[11] On the basis of this study the choice of catheter may be more important if the anaesthetist chooses to use continuous infusion of weak solutions of local anaesthetic. A multi-orifice catheter would appear to reduce the risk of the patient developing unilateral extradural block and may be preferable when administering local anaesthetic by continuous infusion at a rate of $20\ \text{ml h}^{-1}$.

Transient neurological symptoms after spinal anaesthesia with 4% mepivacaine and 0.5% bupivacaine

A. HILLER AND P. H. ROSENBERG

Summary

Several studies have reported transient neurological symptoms after spinal anaesthesia with 5% lignocaine. In order to evaluate the role of concentrated solutions of local anaesthetic in the development of transient neurological symptoms, 200 ASA I or II patients undergoing minor orthopaedic or rectal surgery under spinal anaesthesia were allocated randomly to receive 4% mepivacaine 80 mg or hyperbaric 0.5% bupivacaine 10 mg. All patients were interviewed by an anaesthetist approximately 24 h after spinal anaesthesia, and after 1 week patients were asked to return a written questionnaire. The incidence of transient neurological symptoms consisting of pain in the buttocks or pain radiating symmetrically to the lower extremities differed ($P<0.001$) between patients receiving mepivacaine (30%) and those receiving bupivacaine (3%). Hyperbaric 0.5% bupivacaine can be recommended for minor operations on the lower abdomen or lower extremities. (*Br. J. Anaesth.* 1997; **79**: 301–305).

Key words
Anaesthetic techniques, subarachnoid. Anaesthetics local, mepivacaine. Anaesthetics local, bupivacaine. Complications, neurological.

The first report of transient neurological symptoms, termed initially transient neurological impairment or transient radicular irritation, after spinal anaesthesia with hyperbaric 5% lignocaine by Schneider and colleagues in 1993[1] was confirmed later by several other studies.[2–6] It is thought that a localized local anaesthetic toxic effect may be an important contributing factor in the development of transient neurological symptoms after spinal anaesthesia with concentrated solutions.[7 8] The occurrence of this complication is rare after the use of 0.5% bupivacaine for spinal anaesthesia.[5 9 10]

Mepivacaine has been used for spinal anaesthesia since the beginning of the 1960s.[11] In the first large-scale report of 20 000 mepivacaine spinal anaesthetics, outcome was favourable and no neurological complications were noted.[12] However, as with 5% hyperbaric lignocaine, the hyperbaric spinal anaesthetic solution of mepivacaine is also quite concentrated (4%) and post-spinal sequelae similar to those after hyperbaric lignocaine spinal anaesthesia should be expected. In this study, we examined the occurrence of transient neurological symptoms after spinal anaesthesia with either 4% hyperbaric mepivacaine or hyperbaric 0.5% bupivacaine.

Patients and methods

Two hundred ASA I or II patients undergoing minor orthopaedic, varicose vein, rectal or gynaecological operations were studied in a randomized, double-blind manner (table 1). Patients with a pre-existing neurological disease or diabetes mellitus were excluded. The study was approved by the Ethics Committee of the hospital, and informed consent was obtained from the patients.

All patients were premedicated with diazepam 5–15 mg orally. Patients were allocated randomly by sealed envelope to receive 4% mepivacaine 80 mg with glucose 95 mg ml^{-1} (Scandicain 40 mg ml^{-1}, Astra, Wedel, Germany) or 0.5% hyperbaric bupivacaine 10 mg with glucose 80 mg ml^{-1} (Marcain spinal 5 mg ml^{-1}, Tung, Astra, Södertälje, Sweden). An identical volume of 2 ml was drawn into a syringe by an independent anaesthesia nurse so that the anaesthetist (A. H.) performing the block was unaware of which drug was given. Although the doses are not equipotent from a theoretical point of view, similar spread and duration of spinal anaesthesia have been observed after a dose of 10 mg of 0.5 % hyperbaric bupivacaine and 80 mg of hyperbaric mepivacaine.[13 14]

A peripheral i.v. infusion with acetated Ringer's solution was started before operation. Thereafter spinal anaesthesia was performed at the L3–4 interspace with the patient in the lateral position using a 27-gauge Quincke needle. However, if the puncture was considered difficult, a higher interspace, larger needle or the sitting position was chosen to perform spinal anaesthesia. Free flow of cerebrospinal fluid was verified before and after injection of the local anaesthetic. Immediately after spinal puncture, the patient was turned to the supine position with the operating table in a slight head-up tilt position.

Correspondence to A. H.

Patients were monitored with electrocardiography, automated arterial pressure and pulse oximetry. Hypotension (systolic arterial pressure <90 mm Hg or >30% decrease from baseline) was treated with 5-mg increments of ephedrine or 200-μg increments of phenylephrine. Bradycardia (heart rate <50 beat min^{-1}) was treated with atropine 0.5 mg or glycopyrronium 0.2 mg.

Testing of pinprick analgesia and motor block was performed at 5, 10, 15, 60 min, and thereafter at 30-min intervals. A modified Bromage scale was used for testing motor block: 0=no paralysis (full flexion of the knees and feet), 1=inability to flex the extended leg (just able to move the knees), 2=inability to flex the knee (able to move the feet only), 3=inability to flex the ankle joint (unable to move the feet or knees). Patients were discharged from the recovery room when recovery of motor block was complete. Nurses on the ward recorded the time when patients reported that they had normal sensation in the buttocks and feet.

All patients were interviewed by the investigator on the first postoperative morning. They were asked if they had experienced any of the symptoms on the following standardized symptom checklist: headache, backache, pain not associated with surgery, sensory disturbances, change in muscle strength, or difficulties in voiding or in hearing. Special attention was paid to lower extremity symptoms, type of pain and radiation of pain.[3]

One week after spinal anaesthesia, patients were asked to return a mailed questionnaire. They were asked to mention symptoms which they particularly associated with spinal anaesthesia. Enquiries concerning symptoms and their duration included headache, backache, pain in the operation area and pain in the thighs, buttocks, calves or elsewhere. Patients were also asked to assess the degree of satisfaction with their spinal anaesthesia.

Transient neurological symptoms were defined as symmetrical bilateral pain in the back or buttocks or pain radiating to the lower extremities after recovery from spinal anaesthesia.

Student's t test and Fisher's exact test were used to compare differences. $P<0.05$ was considered significant.

Results

The characteristics of the patients and details of the operations and spinal anaesthetic procedures are summarized in tables 1 and 2. Motor block was complete in 96% of patients in the mepivacaine group and in 81% of patients in the bupivacaine group ($P<0.001$). Details of motor block are presented in table 3. In one case, bupivacaine provided inadequate surgical anaesthesia although free flow of cerebrospinal fluid was verified before and after injection of the drug.

Eighty-nine of 99 (90%) patients in the mepivacaine group and 88 of 99 (89%) patients in the bupivacaine group returned the questionnaire. Twelve patients in the mepivacaine group and two patients in the bupivacaine group were not satisfied with their spinal anaesthesia ($P<0.05$). Two patients who had received mepivacaine spinal anaesthesia had headache at home, one for 3 days and the other for 1 week. Neither needed an extradural blood patch. Two patients who had received bupivacaine spinal anaesthesia reported transient deterioration in hearing.

The incidence of transient neurological symptoms differed ($P<0.001$) between patients who received

mepivacaine (30%) and those who had received bupivacaine (3%). The mean age of patients with transient neurological symptoms in the mepivacaine group was 44 (range 21–68) yr and in the bupivacaine group 51 (47–54) yr. Mean weight was 77 (56–105) kg in the mepivacaine group and 77 (75–80) kg in the bupivacaine group. There was no association between the incidence of transient neurological symptoms and patient sex, weight or age. All patients who experienced transient neurological symptoms had been in the supine position during operation, except for one who was in the lithotomy position. Furthermore, in all patients with transient neurological symptoms the spinal puncture had been performed in the lateral position. There was no association between transient neurological symptoms and difficulty of block placement or paraesthesia. In all three patients in the bupivacaine group and in 26 of 30 patients with symptoms in the mepivacaine group, pain occurred within the first 24 h. In one patient who had both pain and dysaesthesia in the buttocks, symptoms lasted for 5 days. In 14 patients in the mepivacaine group and in one patient in the bupivacaine group, pain was relieved by non-steroidal anti-inflammatory drugs; nine patients also needed opioids. Five patients reported that the pain was worse in the supine position and it was relieved when they stood up and started to walk (table 4).

No patient had sensory disturbances, change in muscle strength or difficulties in voiding on the first postoperative morning.

Three patients who had transient neurological symptoms after mepivacaine spinal anaesthesia had experienced similar symptoms before, one after 5% hyperbaric lignocaine spinal anaesthesia and two after 4% hyperbaric mepivacaine anaesthesia. All three patients who had transient neurological symptoms in the bupivacaine group returned the questionnaire and were satisfied with the spinal anaesthesia. In the mepivacaine group, 27 of 30 patients returned the questionnaire and 20% were not satisfied with spinal anaesthesia; four because of transient neurological symptoms, one because of painful puncture and one patient complained of difficulty in breathing because of the maximum height of block (T4) during operation.

All complaints were transient and had disappeared by the time the patients mailed the questionnaire.

Discussion

In this study, transient neurological symptoms occurred in 30% of patients who received spinal anaesthesia with mepivacaine but also in 3% of patients who received spinal anaesthesia with hyperbaric bupivacaine. However, duration of symptoms after bupivacaine spinal anaesthesia was less than 12 h compared with 12–120 h after mepivacaine spinal anaesthesia.

In 1993, Schneider and colleagues published the first case reports of transient neurological symptoms after spinal anaesthesia with 5% hyperbaric lignocaine.[1] Other later studies have shown similar symptoms, termed transient radicular irritation (TRI) after 5% hyperbaric lignocaine spinal anaesthesia in 10–37% of patients.[2–5] Thus the incidence of transient neurological symptoms or TRI after concentrated solutions of 4% mepivacaine and 5% lignocaine is similar. In the study of Pollock and colleagues the incidence of TRI was 16% after both

5% hyperbaric lignocaine and 2% lignocaine without glucose, but 0% after 0.75% hyperbaric bupivacaine.[5] In the study by Tarkkila, Huhtala and Tuominen, only one of 110 patients had TRI after 0.5% hyperbaric bupivacaine.[10] The neurotoxic potential of 5% hyperbaric lignocaine and 0.75% bupivacaine has been evaluated.[7] Exposure of amphibian nerves to 0.75% isobaric bupivacaine produced partially reversible conduction block, whereas 5% lignocaine with or without glucose caused irreversible block of impulses.[7] Furthermore, it has been shown in an *in vitro* study that lignocaine 80 mmol, which is equivalent to a concentration of 2% lignocaine, caused complete ablation of impulse activity.[8] In clinical studies, decreasing the concentration of lignocaine from 5% to 2% did not prevent the development of TRI.[5 15]

The doses of mepivacaine and bupivacaine in our study were based on the clinical study of Pitkänen, Kalso and Rosenberg, where 80 mg (2 ml) of 4% hyperbaric mepivacaine resulted in spinal anaesthesia similar to that after a dose of 0.5% hyperbaric bupivacaine 10 mg (2 ml) or 0.5% hyperbaric lignocaine 100 mg (2 ml).[14] Also, spinal anaesthesia with mepivacaine 60 mg produced analgesia and motor block of good quality but of short duration compared with spinal anaesthesia with 0.5% hyperbaric bupivacaine 15 mg.[16] Decreasing the dose of mepivacaine from 80 to 60 mg may diminish the development of transient neurological symptoms and still provide adequate anaesthesia for operations on the lower extremities.

Lambert, Lambert and Strichartz demonstrated synergistic neurotoxic effects of lignocaine and glucose *in vitro*, in frog sciatic nerve.[7] The loss of neural activity was not found to correlate with the glucose concentration and inhibition could not be induced without local anaesthetic. The hyperbaric mepivacaine solution has a higher concentration of glucose (95 mg ml^{-1}) compared with hyperbaric lignocaine (62.5 mg ml^{-1}) or hyperbaric bupivacaine (80 mg ml^{-1}). The greater the baricity of the solution the greater the chance of gravity-determined spread restriction. This, together with the use of small gauge pencil-point needles with one side hole near the tip, could result in pooling of the concentrated local anaesthetic solution. Repeated injections through thin intrathecal catheters may, therefore, result in cauda equina syndrome.[17] Beardsley and colleagues showed that sacral direction of the needle orifice and a slow injection rate with a Whitacre needle may be predisposing factors to transient neurological complications with 5% hyperbaric lignocaine.[18] However, other studies have failed to confirm this.[3 10] In contrast, in this study we injected via Quincke-type needles (orifice at the bevelled tip) and initial directional pooling of the local anaesthetic in the sacral region was unlikely.

In addition to a toxic effect of the local anaesthetic, the lithotomy position during surgery has been thought to be a possible cause of transient neurological symptoms.[1 4 10] The lithotomy position may contribute to transient neurological symptoms by stretching the cauda equina and sciatic nerves, thus decreasing the vascular supply and increasing vulnerability to injury. In our study, four patients in the bupivacaine group and two in the mepivacaine group were in the lithotomy position during surgery. Only one patient in the mepivacaine group had transient neurological symptoms starting 24–48 h after anaesthesia. However, transient neurological symptoms occurred in 22 patients undergoing arthroscopy of the knee. In our hospital, arthroscopy patients have both legs straight at the hip, and flexed 90° at the knee. The operative leg position is varied throughout surgery. The position and manipulation may contribute to neural stretching and thus to the development of transient neurological symptoms. Also, Pollock and colleagues found a higher incidence of transient neurological symptoms in patients undergoing arthroscopy than in those having inguinal hernia repair.[5]

Individual physical characteristics of patients may predispose to the development of transient neurological symptoms after spinal anaesthesia. Interestingly, in this study three patients who had transient neurological symptoms after mepivacaine spinal anaesthesia had experienced similar symptoms before, one after 5% hyperbaric lignocaine and two after 4% hyperbaric mepivacaine spinal anaesthesia. It has been shown that the anatomical configuration of the spinal column affects the spread of subarachnoid anaesthetic solutions that move under the influence of gravity.[19 20] Both lumbar lordosis and thoracic kyphosis differ between individuals, particularly with respect to the lowest point of the thoracic spinal canal.[21] Musculoskeletal disturbances in the back and leg symptoms cannot be totally excluded. We speculate that profound relaxation of the supportive muscles of the lumbar spine may result in straightening of the lordotic curve, and even transient spondylolisthesis, when the patient is lying on the operating table. This may be responsible in part for the radiating back symptoms which occurred after the intense motor block, observed during mepivacaine spinal block in particular.

In summary , the incidence of transient neurological symptoms was greater after spinal anaesthesia with 4% hyperbaric mepivacaine than after 0.5% hyperbaric bupivacaine. Patients were more satisfied with bupivacaine spinal anaesthesia. Except for a greater number of complete motor blocks after mepivacaine, spinal anaesthesia and recovery were similar after both agents. Therefore, hyperbaric 0.5% bupivacaine 10 mg can be recommended for minor operations on the lower extremities or lower abdomen lasting less than 90 min.

Comparison of volume controlled with pressure controlled ventilation during one-lung anaesthesia

M. TUĞRUL, E. ÇAMCI, H. KARADENİZ, M. ŞENTÜRK, K. PEMBECİ AND K. AKPİR

Summary

Pressure controlled ventilation (PCV) is an alternative mode of ventilation which is used widely in severe respiratory failure. In this study, PCV was used for one-lung anaesthesia and its effects on airway pressures, arterial oxygenation and haemodynamic state were compared with volume controlled ventilation (VCV). We studied 48 patients undergoing thoracotomy. After two-lung ventilation with VCV, patients were allocated randomly to one of two groups. In the first group (n=24), one-lung ventilation was started by VCV and the ventilation mode was then switched to PCV. Ventilation modes were performed in the opposite order in the second group (n=24). We observed that peak airway pressure (P=0.000001), plateau pressure (P=0.01) and pulmonary shunt (P=0.03) were significantly higher during VCV, whereas arterial oxygen tension (P=0.02) was significantly higher during PCV. Peak airway pressure (Paw) decreased consistently during PCV in every patient and the percentage reduction in Paw was 4–35% (mean 16.1 (SD 8.4) %). Arterial oxygen tension increased in 31 patients using PCV and the improvement in arterial oxygenation during PCV correlated inversely with preoperative respiratory function tests. We conclude that PCV appeared to be an alternative to VCV in patients requiring one-lung anaesthesia and may be superior to VCV in patients with respiratory disease. (*Br. J. Anaesth.* 1997; **79**: 306–310).

Key words
Ventilation, one-lung. Ventilation, volume controlled. Ventilation, pressure controlled.

During one-lung anaesthesia, arterial hypoxaemia is a major concern.[1] Volume controlled ventilation (VCV) is the traditional method of performing one-lung anaesthesia in patients undergoing thoracic surgery and an increase in airway pressure is usually observed. If the method of ventilation involves excessive amounts of airway pressure, vascular resistance of the dependent lung may be increased because of compression of intra-alveolar vessels.[2] Thus high airway pressures of the dependent lung may counteract hypoxic pulmonary vasoconstriction in the non-dependent lung by diverting blood flow away from the ventilated lung, thereby increasing pulmonary shunt fraction.[3]

One-lung ventilation implies delivering the entire tidal volume into one lung, which may result in barotrauma of the dependent lung. In order to avoid high airway pressures, anaesthetists may ventilate the dependent lung with lower tidal volumes and higher ventilatory frequencies during one-lung anaesthesia. However, lower tidal volumes have been demonstrated to predispose the dependent lung to atelectasis and worsen arterial oxygenation.[4 5]

Pressure controlled ventilation (PCV) is an alternative mode of ventilation which is used widely in severe respiratory failure. PCV has been shown to improve arterial oxygenation and decrease peak airway pressure because of its decelerating inspiratory flow.[6] Uniform distribution of inspired gas with PCV is the major cause of better arterial oxygenation in patients with respiratory failure.[7–10]

We applied PCV to one-lung anaesthesia and examined its use as a tool to improve ventilatory management of patients undergoing thoracic surgery. In our study, PCV was used for one-lung anaesthesia and its effects on airway pressure, arterial oxygenation and haemodynamic state were compared with those produced by VCV.

Patients and methods

The study was approved by the University of Istanbul Ethics Committee and all patients gave informed consent. We studied 48 patients, ASA I–III, undergoing thoracotomy requiring one-lung ventilation. On the evening before surgery, spirometry (forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV_1)) was performed in the sitting position. An arterial blood-gas sample was also obtained with the patient breathing air. Patients were excluded if they had a history of cardiac, hepatic or renal disease.

All patients were premedicated with diazepam 0.15 mg kg^{-1} orally, 1 h before arrival in the operating room. On admission to the operating room, i.v.

and intra-arterial cannulae were inserted under local anaesthesia and an ECG was attached. After pre-oxygenation, anaesthesia was induced with fentanyl 2 $\mu g\ kg^{-1}$ and propofol 2–2.5 $mg\ kg^{-1}$; tracheal intubation was facilitated with vecuronium 0.1 mg kg^{-1}. The trachea was intubated with an Univent tracheal tube (Fuji Corp, Japan). The bronchial blocker of the Univent tube was inserted into the mainstem bronchus of the operative side guided by a fibreoptic bronchoscope and separation of the lungs was demonstrated by capnography.[11] With this method, the tracing from the end-tidal carbon dioxide analyser connected to the proximal end of the bronchial blocker of the Univent shows a typical respiratory waveform. As the bronchial blocker cuff is gradually inflated, a straight line on the waveform indicates that lung isolation has occurred.

After induction of anaesthesia a 7-F pulmonary artery catheter (Abbott, Criticare Systems, USA) was inserted via the right internal jugular vein. Isoflurane 1–1.5%, fentanyl 0.05–0.1 $\mu g\ kg^{-1}\ min^{-1}$ and vecuronium 0.03 mg kg^{-1} every 30 min were used for maintenance of anaesthesia. Fentanyl bolus doses of 50–100 μg and i.v. fluids were administered to maintain systemic arterial pressure within ±20% of pre-induction values. Oesophageal temperature was monitored throughout the procedure and maintained greater than 36.5 °C by a heating blanket (Biçakçilar, Turkey) placed under the patient.

Our study consisted of three steps. Two-lung ventilation (TLV) with VCV (TLV-VCV) was performed in the lateral decubitus position in all patients (Servo 900C, Siemens, Stockholm, Sweden). On initiation of one-lung ventilation, patients were allocated randomly to one of two groups. In the first group ($n=24$), one-lung ventilation was started by VCV (OLV-VCV) and the ventilation mode was then changed to PCV (OLV-PCV). The modes of ventilation were performed in the opposite order in the second group ($n=24$).

During TLV-VCV and OLV-VCV, patients' lungs were ventilated with a tidal volume of 10 ml kg^{-1} and ventilatory frequency was adjusted to maintain arterial carbon dioxide tension (Pa_{CO_2}) at 4.5–6 kPa. PCV was initiated with a peak airway pressure that provided a tidal volume of 10 ml kg^{-1}. Ventilatory frequency was adjusted to maintain Pa_{CO_2} at 4.5–6 kPa during OLV-PCV. With both PCV and VCV, we used a 25% inspiratory time and a 10% pause time. Inspiratory oxygen concentration (FI_{O_2}) was adjusted to 0.5 in air during two-lung ventilation and to 1.0 during one-lung ventilation. End-tidal concentrations of carbon dioxide and isoflurane were monitored using a Criticare 1100 (Criticare Inc, USA).

In accordance with data obtained from previous studies,[12 13] all measurements were made 30 min after initiation of the ventilation mode. All operations were performed by the same surgical team and the study was completed before any pulmonary vessels were ligated. Measurements were completed during the minutes in which the surgeons stopped compressing the operative lung.

The following variables were measured and recorded at the end of each period. Arterial and venous oxygen tensions and saturations (Pa_{O_2}, Sa_{O_2}, $S\bar{v}_{O_2}$), Pa_{CO_2} and haemoglobin (Hb) were analysed within 5 min using ABL 505 and OSM3 Hemoximeter (Radiometer, Copenhagen, Denmark). Heart rate (HR), mean arterial pressure (MAP), pulmonary artery pressure (MPAP), central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) were recorded from the Criticare 1100 (Criticare Inc, USA). Deltran II transducers (Utah Medical, USA) were used to measure pulmonary arterial and systemic pressures. The zero reference was the mid-chest level and vascular pressures were measured at end-expiration. Cardiac output (CO) was measured by a thermodilution technique using injection of 10 ml of 0.9% saline at 0 °C (Abbott Criticare Systems, USA). The mean value of three measurements was obtained. Pulmonary shunt (Qs/Qt) was calculated from standard formulae.[14]

Peak airway pressure (Paw) and mean airway pressure (Pmaw) were recorded during each mode of ventilation. Inspiratory plateau was established by activating the inspiratory hold on the Siemens Servo 900C ventilator. Inspiratory plateau pressure (Pplt) was measured during the last 0.3 s of each hold manoeuvre.

We studied Pa_{O_2} data in order to identify which patients would benefit from OLV-PCV. The relationship between "individual Pa_{O_2} differences between OLV-PCV and OLV-VCV" and respiratory function tests was studied by linear regression analysis.

Data are presented as mean (SD). Paired Student's t test, ANOVA and chi-square test were used to test the significance of the differences between groups. Statistical significance was assumed at $P=0.05$.

Results

Patient data are shown in table 1. Mean values for ventilation, gas exchange and haemodynamic variables at each time are presented in tables 2 and 3. During one-lung ventilation, arterial hypoxaemia (Sa_{O_2} <90%) requiring reinflation of the collapsed lung did not occur in any patient.

Pa_{CO_2}, Sa_{O_2}, $S\bar{v}_{O_2}$, Hb, MAP, MPAP, PAOP, CVP and CO did not differ significantly between any of the ventilation modes.

Comparison of the OLV-VCV and OLV-PCV modes revealed significant differences in Paw, Pplt,

Pa_{O_2} and *Qs*/*Qt*. *P*aw was significantly lower during OLV-PCV than during OLV-VCV (23.65 (3.85) cm H_2O *vs* 28.3 (5.1) cm H_2O) ($P=0.000001$). Compared with OLV-VCV, *P*aw decreased consistently during OLV-PCV in every patient, ranging from 1 to 13.5 cm H_2O. The percentage *P*aw difference was 4–35% (mean 16.1 (8.4) %). *P*plt was also significantly lower during OLV-PCV than during OLV-VCV (17.8 (3.7) *vs* 18.5 (4.2) cm H_2O) ($P=0.01$) .

Mean Pa_{O_2} was significantly higher during OLV-PCV (32.3 (14.4) kPa *vs* 28.4 (15.6) kPa) ($P=0.03$) than during OLV-VCV. Arterial oxygenation improved in 31 patients with OLV-PCV and in 17 patients with OLV-VCV ($P=0.008$). Twenty-three of 31 patients (74%) who had an improved Pa_{O_2} value with OLV-PCV had an FVC lower than 77%, whereas only six of 17 (35%) patients who had an improved Pa_{O_2} with VCV had an FVC lower than 77% ($P=0.02$). Also, 19 of 31 patients (61%) whose Pa_{O_2} improved with OLV-PCV had an FEV_1 lower than 77%, whereas five of 17 (30%) patients whose Pa_{O_2} improved with OLV-VCV had an FVC lower than 77% ($P=0.07$). On the basis of linear regression analysis "individual Pa_{O_2} difference between OLV-PCV and OLV-VCV" showed a significant correlation with FVC ($r=-0.30$, $P=0.02$) (fig. 1), but no significant correlation with FEV_1 ($r=-0.24$, $P=0.09$).

Mean *Qs*/*Qt* was significantly higher during OLV-VCV (40.2 (10.1) *vs* 36.2 (10) %, $P=0.02$) than during OLV-PCV. *Qs*/*Qt* was found to be higher during OLV-VCV in 32 patients, whereas OLV-PCV resulted in higher *Qs*/*Qt* values in only 16 patients ($P=0.002$).

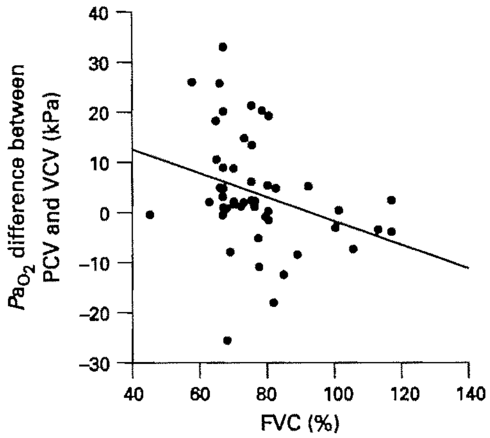

Figure 1 Individual Pa_{O_2} difference between PCV and VCV *vs* FVC (forced vital capacity) ($r=-0.30$, $P=0.02$) ($y=168.6-1.8x$).

Discussion

VCV is the common mode of ventilation used in patients undergoing one-lung anaesthesia. In our study, we performed pressure controlled ventilation to overcome some of the problems observed with one-lung anaesthesia. We planned to use almost the same tidal volumes to examine the effects of each mode on airway pressures, pulmonary shunt and arterial oxygenation. As tidal volumes greater than 10 ml kg^{-1} were reported to increase airway pressure and pulmonary vascular resistance in the dependent lung,[5 15 16] we chose a tidal volume of 10 ml kg^{-1} for the dependent lung which was reported to be least detrimental to arterial oxygenation.[17] As it has been documented previously that Pa_{O_2} tends to increase over 1 h after the onset of one-lung anesthesia,[18] we randomized the order of PCV and VCV.

High airway pressures may lead to barotrauma of the dependent lung.[19] It has been reported that high peak inspiratory pressure has some influence on the incidence of barotrauma[20] and avoiding high peak inspiratory pressures seems to be a safe form of ventilation.[21] In our study, peak inspiratory pressures were consistently lower during PCV. A reduction in peak inspiratory pressure of 4–35% induced by PCV is an advantage for one-lung anaesthesia.

It has been demonstrated previously that PCV is associated with sustained reductions in peak inspiratory pressure because of its decelerating flow profile.[7 8] In studies performed in patients with respiratory failure, peak inspiratory pressure was shown to decline from 38 to 33 cm H_2O[9] and from 43 to 40 cm H_2O[10] by PCV. The beneficial effects of reduced peak inspiratory pressures during PCV in terms of minimizing lung injury have been attributed to concomitant reductions in peak alveolar pressure and consequent decreases in alveolar distension.[22] However, there are no studies comparing the incidence of iatrogenic lung injury using PCV or VCV. It was postulated that the very rapid initial flows with PCV may cause different effects on filling patterns, and thus the risk of barotrauma from shearing may be less using pressure *vs* volume breaths.[23]

There is a growing tendency to define end-inspiratory plateau pressure as a more important determinant of barotrauma than peak airway pressure.[24] In our study, plateau pressure was found to be significantly lower during PCV. Furthermore, it is possible during VCV for some alveoli to receive higher pressures during inspiration than the end-inspiratory plateau pressure. In contrast, in no parts of the lung can the pressure be higher than the preset pressure during PCV.[22]

Because of the high peak inspiratory pressures usually observed with the initiation of one-lung anaesthesia, most anaesthetists tend to ventilate the dependent lung with lower tidal volumes and higher respiratory frequencies aiming to protect the dependent lung from hyperinflation. However, lower tidal volumes have been demonstrated to predispose the dependent lung to develop atelectasis, thereby worsening arterial oxygenation.[4,5] We assume that lower airway pressures obtained with PCV allow the use of higher tidal volumes during one-lung anaesthesia.

Factors that play a role in the hypoxaemia frequently seen during one-lung anaesthesia include reduction in dependent lung volume caused by induction of anaesthesia, abdominal and mediastinal compression, suboptimal positioning, low ventilation: perfusion ratios and atelectasis because of a high FI_{O_2}, and problems in removal of secretions.[25] Hypoxic pulmonary vasoconstriction is an autoregulatory mechanism that diverts blood flow away from hypoxic, atelectatic lung towards the remaining normoxic, ventilated lung and it is very effective in reducing hypoxic lung blood flow when the percentage hypoxic lung is intermediate (30–70%), that is the amount of lung that is hypoxic during one-lung anaesthesia.[26]

Compression of small intra-alveolar vessels during inflation of alveoli produces increased resistance to pulmonary blood flow in the dependent lung. This increase in vascular resistance may divert blood flow to the non-ventilated alveoli of the non-dependent lung. Further increases in tidal volume and airway pressure in the dependent lung are then unlikely to improve oxygenation and may make arterial oxygenation worse by diverting blood flow to the non-dependent lung.[4,16,17] Although not necessarily reflecting intra-alveolar pressure, the high peak and plateau pressures observed with VCV in our study may play a role in diverting blood flow to the non-dependent lung and produce a higher pulmonary shunt.

One of the aims of this study was to investigate the effects of PCV on arterial oxygenation during one-lung anaesthesia. It was demonstrated earlier that improvement in arterial oxygenation by PCV was not related to variations in mean airway pressure but resulted mostly from the beneficial effects of the decelerating inspiratory flow pattern produced by PCV on the distribution of gas within the lung.[7] In diseased lungs with different time constants, the decelerating flow of PCV sustains alveolar pressure longer than the constant flow of VCV, thereby aiding recruitment and improving homogenous distribution of inspired gas. In our study, Pa_{O_2} improved in most patients during PCV and mean Pa_{O_2} was significantly higher than that during VCV. The improvement in arterial oxygenation during PCV may be explained by the flow profile of this mode and also the lower pulmonary shunt obtained with PCV.

To answer the question "which patients benefited more from PCV" we investigated the correlation between individual Pa_{O_2} differences between PCV and VCV, and respiratory function tests. We found that there was a significant correlation between individual Pa_{O_2} difference between PCV and VCV, and FVC. Patients whose Pa_{O_2} improved with PCV generally had a poor FVC (fig. 1). Many of the studies demonstrating better arterial oxygenation with PCV compared with VCV were performed in patients with severe respiratory failure.[7–9] As may be expected, those patients who had dependent lung pathology of varying severity, especially patients with restrictive disease, benefited from the decelerating flow pattern of PCV which improved distribution of alveolar gas and arterial oxygenation.

Acute effect of mitral valve replacement on extravascular lung water in patients receiving colloid or crystalloid priming of cardiopulmonary bypass

W. BUHRE, A. HOEFT, B. SCHORN, A. WEYLAND, M. SCHOLZ AND H. SONNTAG

Summary

Despite numerous studies on extravascular lung water (EVLW) in patients undergoing coronary artery bypass surgery, few data are available on the perioperative time course of EVLW in patients undergoing mitral valve replacement for mitral valve insufficiency (MVI). We have investigated 26 patients undergoing elective mitral valve replacement in order to determine the influence of the preoperative degree of mitral valve insufficiency (degree III or IV) and the effect of different priming solutions for cardiopulmonary bypass. Crystalloid priming with Ringer's lactate was compared with human albumin priming solution. Measurement of EVLW was performed using the thermo-dye dilution technique, before and 1, 6 and 24 h after surgery. Before operation, EVLW is increased significantly in patients with MVI degree IV (MVI-°IV) compared with patients with degree III (MVI-°III) and patients undergoing coronary artery bypass surgery. During the postoperative time course a significant decrease in EVLW was observed in patients with MVI-°IV whereas in patients with MVI-°III the amount of EVLW did not change. However, compared with patients undergoing coronary artery bypass surgery, EVLW remained above normal in both groups. There was no interaction between the type of priming solution and the postoperative time course of EVLW, and no differences in respiratory variables or duration of mechanical ventilation were observed between groups. Contact of blood with tubing surface material of the cardiopulmonary bypass (CPB) during open heart surgery causes activation of several mediator systems.[1 2] The resulting systemic inflammatory response leads to increased capillary permeability and may cause impairment of myocardial function.[3–6] Therefore, pulmonary oedema is a typical complication after open heart surgery, in particular if a pure crystalloid solution is used for priming the cardiopulmonary bypass.[3 5 7]

In a previous study, we demonstrated that priming of cardiopulmonary bypass with nearly physiological colloid–osmotic pressure attenuated the increase in extravascular lung water (EVLW) compared with a pure crystalloid priming solution in patients undergoing coronary bypass surgery.[8] However, only moderate increases in EVLW were observed in the crystalloid group and pulmonary function variables did not differ between groups.[8] Because of costs, it is therefore questionable to advocate albumin priming for all patients. However, we hypothesized that patients who have additional risk factors for postoperative pulmonary dysfunction may benefit from colloid priming of cardiopulmonary bypass. A group of patients at risk of postoperative pulmonary complications are those with mitral valve insufficiency (MVI) undergoing mitral valve replacement.

Therefore, the aim of this study was to compare the effect of a priming solution with nearly physiological colloid–osmotic pressure (4% albumin) with a pure crystalloid priming solution (Ringer's lactate) on postoperative EVLW content in patients undergoing mitral valve replacement.

Patients and methods

We studied 26 patients undergoing elective surgery for mitral valve replacement. The study was approved by the local Ethics Committee and patients gave fully informed consent. Twelve patients presented with angiographic determined mitral valve insufficiency degree three (MVI-III°, regurgitation fraction >30–50% of stroke volume) and 14 patients with mitral valve insufficiency degree four (MVI-IV°, regurgitation fraction >50% of stroke volume). Patients were allocated randomly to subgroups with a different priming volume for

cardiopulmonary bypass. Consequently, two subgroups (MVI-III°-HA, $n=6$ and MVI-IV°-HA, $n=7$) received a priming volume with near physiological colloid–osmotic pressure. The priming solution consisted of 400 ml of 20% human albumin (HA), Ringer's lactate 1000 ml, 5% glucose 500 ml and bicarbonate 100 ml, resulting in an effective albumin concentration of 4%. The two other subgroups (MVI-III°-RL, $n=6$ and MVI-IV°-RL, $n=7$) received a pure crystalloid priming solution (Ringer's lactate 1400 ml, 5% glucose 500 ml and bicarbonate 100 ml). Cardiopulmonary bypass was performed under conditions of moderate hypothermia (nasopharyngeal temperature 32 °C), and ice-cooled crystalloid cardioplegic solution was used for myocardial protection.

Premedication comprised flunitrazepam 1–2 mg orally on the evening before surgery and also 1 h before arrival in the operating room. After arrival in the anaesthesia induction room, ECG leads II and V5 were attached. A central venous catheter was inserted under local anaesthesia and a 5-F introducer sheet was placed into the right femoral artery for measurement of arterial pressure. General anaesthesia was induced with fentanyl 7 μg kg^{-1} and etomidate 0.3 mg kg^{-1}. Pancuronium 0.1 mg kg^{-1} was given to facilitate tracheal intubation. Tidal volume and inspired fraction of oxygen (FI_{O_2}) were adjusted to maintain normal levels of arterial partial pressure of carbon dioxide (Pa_{CO_2}) and an arterial oxygen saturation (Sa_{O_2}) greater than 95%. Anaesthesia was maintained with fentanyl 6–7 μg kg^{-1} h^{-1} and midazolam 90–105 μg kg^{-1} h^{-1}.

After induction of anaesthesia a 7-F pulmonary artery catheter was introduced into the pulmonary artery via the right internal jugular vein. Additionally, a combined 4-F fibreoptic–thermistor catheter was inserted via the introducer sheet in the femoral artery and advanced 40 cm up the thoracic aorta. Special care was taken to confirm that the position of the catheters did not change during the study. The fibreoptic–thermistor catheters were connected to a commercially available optoelectronic device (Pulsion-COLD system, Pulsion, Munich, Germany) which allows simultaneous detection of thermo- and dye-dilution curves.

Haemodynamic and indicator dilution measurements were performed after induction of anaesthesia and at 1, 6 and 24 h after surgery. Arterial and mixed venous blood samples were obtained for measurement of haemoglobin content, oxygen saturation (OSM-3 haemoximeter, Radiometer, Copenhagen, Denmark) and blood-gas analysis (IL 1302 pH/blood-gas analyser, Instrumentation Laboratory Inc., Lexington, MA, USA). Standard haemodynamic variables (heart rate, arterial, central venous and pulmonary artery arterial pressures) were obtained. Measurements were performed when a steady state condition had been verified for at least 5 min.

Measurements of indicator dilution curves were obtained by triple bolus injections of 10 ml of ice-cooled indocyanine green dye (ICG) 1.25 mg ml^{-1} into the right atrium. Injections were spread randomly over the respiratory cycle. The resulting aortic dye dilution curve and also the two thermodilution curves obtained in the pulmonary artery and aorta were digitized and stored on hard disk (Pulsion COLD system, Fa Pulsion, Munich, Germany).

Extravascular lung water (EVLW) was calculated according to the following formula:

$$\mathrm{EVLW}=\frac{\mathrm{CO}\cdot(\mathrm{mtt}_{\mathrm{cent-thermo}}-\mathrm{mtt}_{\mathrm{cent-dye}})}{\mathrm{BW}} \qquad (1)$$

where CO=cardiac output (litre min^{-1}), $\mathrm{mtt}_{\mathrm{cent-thermo}}$=mean transit time of negative heat between the pulmonary artery and aorta (s), $\mathrm{mtt}_{\mathrm{cent-dye}}$=mean transit time of indocyanine green dye between the pulmonary artery and aorta (s) and BW=body weight (kg).

Cardiac output was calculated from the area under the thermodilution curve (Stewart–Hamilton method). Calculation of mean transit time ($\mathrm{mtt}_{\mathrm{cent-thermo}}$, $\mathrm{mtt}_{\mathrm{cent-dye}}$) requires exclusion of recirculating indicator from the dye- and thermodilution curves.[7 8] Conventionally, mathematical exclusion of recirculation is accomplished by mono-exponential extrapolation of the downslope of the indicator dilution curve between 70 and 30% of maximum height.[8 9] It has been demonstrated by our group that this approach carries a systematic error for thermodilution measurements, which leads to overestimation of $\mathrm{mtt}_{\mathrm{cent-thermo}}$ because of incomplete elimination of recirculation and insufficient exclusion of pre-pulmonary thermo-accessible volume.[8 9] Therefore, in this study we used an alternative approach which is based on stochastical analysis, as suggested by Böck and colleagues.[9] The mathematical background of this technique has been described in detail in previous publications by our group and also by others.[8–11]

Briefly, the relation between the output (aortic indicator dilution curve) and input (pulmonary indicator dilution curve) of the system can be described mathematically by a convolution integral (eqn (2)):

$$C_{ao}(t)=\int_{0}^{t} h(t-u)\cdot C_{\mathrm{pulm}}(u)d(u) \qquad (2)$$

whereas C_{ao} (t)=calculated concentration–time course of an aortic indicator dilution curve (output) depending on the concentration–time course of the indicator measured in the pulmonary artery (C_{pulm}) (input).[8] The pulmonary transport function (h (t)) characterizes the indicator dispersion during passage through the lung. In this study, aortic and pulmonary thermodilution curves were measured, and the pulmonary transport function (h (t)) was calculated from these curve.[8] Basically, the pulmonary transport function was determined by iterative convolution of the pulmonary artery thermodilution curve with a lagged normal density function using a non-linear least square algorithm.[8] The advantage of this approach is that determination of mean transit time ($\mathrm{mtt}_{\mathrm{cent-thermo}}$) through the pulmonary circulation is independent of recirculating indicator as the mean transit time is a variable of transport function.[9 10] In a previous study[8] we applied the convolution technique for both indicators, thermal and dye, but analysis of the data revealed that $\text{mtt}_{\text{cent-dye}}$ values did not differ significantly if elimination of systemic recirculation was performed by monoexponential extrapolation or by the deconvolution approach.[12] Therefore, in this study pulmonary measurements of the dye curves were not deemed necessary as elimination of recirculation could be performed adequately by monoexponential extrapolation of the aortic dye curves.

STATISTICAL ANALYSIS

All data are presented as mean (SD). Two-tailed Student's *t* test for unpaired data were used to compare biometric data and data on cardiopulmonary bypass and ischaemic arrest. The effects of colloid compared with crystalloid priming and the effect of mitral valve insufficiency (MVI-°III compared with MVI-°IV) were tested by two-way analysis of variance for repeated measurements (ANOVA, Statistica Ver. 3.1, Statsoft Inc.). $P \leqslant 0.05$ was considered significant. *Post-hoc* testing within each group and between groups was performed when a significant interaction between repeated measures factor and type of priming solution or degree of mitral valve failure was found. Tukey HSD test was used for *post-hoc* comparison and $P < 0.05$ was considered significant.

Results

There were no significant differences between groups in biometric data, duration of heart arrest and time until tracheal extubation (table 1). Pooled cardiopulmonary data for patients with degree III or IV mitral valve insufficiency and for crystalloid or colloid priming of the cardiopulmonary bypass are presented in tables 2 and 3 and figure 1.

There were no significant differences between groups or subgroups for any of the haemodynamic variables. Heart rate, central venous pressure and cardiac index increased significantly at 1, 6 and 24 h after surgery (tables 2, 3). Mean arterial pressure (MAP) increased slightly 1 and 24 h after surgery. Pulmonary capillary wedge pressure did not

decrease significantly after surgery despite mitral valve replacement.

In pooled data, stroke volume index decreased 1 h after surgery (table 3). The decrease occurred mainly in patients receiving a crystalloid priming for the extracorporeal circuit and was statistically significant only for this group despite the degree of mitral valve insufficiency (table 3). After initial fluid replacement in the intensive care unit, SVI reached preoperative values 6 h after operation (table 2).

As expected, EVLW increased in all patients before surgery, compared with values in patients undergoing coronary artery bypass surgery (10.8 (3.9) *vs* 3.6 (1.0) ml kg^{-1}).[8] Moreover, there was a significant difference in EVLW between patients with mitral valve disease of degree III or IV (7.6 (2.0) *vs* 13.6 (2.9) ml kg^{-1}; $P<0.01$) (fig. 1, table 3). EVLW decreased significantly in the subgroup of patients with mitral valve failure degree IV ($P<0.01$, fig. 1), whereas values remained unchanged in patients with mitral valve failure degree III (fig. 1, table 3). In both groups of patients, EVLW values remained above normal compared with patients undergoing coronary artery bypass surgery.[8 12] The type of priming solution for cardiopulmonary bypass did not influence the postoperative time course of EVLW (fig. 1, table 3).

Pre- and postoperative Pa_{O_2}/FI_{O_2} ratios did not differ in patients with MVI-°III compared with those with MVI-°IV (table 3). After extubation, a significant decrease in Pa_{O_2}/FI_{O_2} ratio was observed, but there was no interaction between type of priming volume and Pa_{O_2}/FI_{O_2} ratio. The time to tracheal extubation did not differ between groups or subgroups of patients (table 1).

Discussion

We have demonstrated that EVLW was increased before operation in patients with mitral valve insufficiency compared with patients undergoing coronary artery bypass surgery.[7 8] The amount and perioperative time course of EVLW depended primarily on the degree of mitral valve insufficiency, whereas there was no significant influence of the type of priming solution on the postoperative time course of EVLW.

Accumulation of EVLW in patients after cardiopulmonary bypass has been described by several authors. However, most of these studies were performed in patients undergoing coronary artery bypass surgery.[7 8 13–18] Despite different measurement techniques and a wide range of absolute values, postoperative changes in EVLW were comparable in most studies, that is EVLW accumulation occurred mainly during the first 6 h after surgery.[7 8 14–18]

Mitral valve insufficiency leads to regurgitation of blood which may influence the shape of the aortic indicator dilution curve. For instance, it is well known that tricuspid valve insufficiency may lead to a systematic error in the assessment of cardiac output obtained in the pulmonary artery.[19 20] In this study, tricuspid insufficiency was excluded by preoperative echocardiographic examinations in all patients. Interestingly, there was good agreement for cardiac output values determined from pulmonary and aortic thermodilution curves. Obviously, the presence of mitral valve insufficiency does not necessarily affect determination of cardiac output values from aortic indicator dilution curves.

As described by Hoeft and colleagues[8] and Mehlhorn and colleagues[12] in more detail, the double indicator dilution technique with only a single site of measurement and monoexponential extrapolation of tracer curves leads to overestimation of EVLW. Therefore, in our investigation the convolution approach with two sites of measurements and simultaneous detection of thermodilution curves in the pulmonary artery and aorta was used for calculation of the pulmonary transport function of the thermal indicator.[9 10] Using this method, mean transit time can be calculated on the basis of the pulmonary transport function, and errors caused by insufficient elimination of recirculation can be avoided.[8–10]

Another possible source of error in the determination of EVLW could be the dependency of the calculated values from actual cardiac output. Wickerts and co-workers have demonstrated that the dependency of EVLW from cardiac output is not present when a system with combined, simultaneous fibreoptic–thermistor catheters is used.[21] Therefore, the dependency of EVLW measurements from cardiac output was a problem associated with the first generation of "lung water computers" which used an extracorporeal densitometer for dye detection.[21 22]

Hoeft and colleagues showed that addition of albumin in a sufficiently high concentration to the priming solution of the cardiopulmonary bypass attenuates accumulation of EVLW after CPB in patients undergoing coronary artery bypass surgery.[8] However, the clinical significance of this finding is unclear because the small differences in lung water accumulation between groups were not associated with differences in pulmonary function variables in the study of Hoeft and colleagues.[8] In a study by Hachenberg and co-workers in patients undergoing coronary artery bypass surgery, oxygenation was moderately impaired, as indicated by an increase in the alveolar–arterial oxygen gradient and increased venous admixture. Changes in gas exchange and EVLW do not correlate.[7] Until now, it seems questionable—mainly because of cost—if the use of high colloid priming solutions should be advocated in patients without preoperative pulmonary dysfunction.[7 8] Thus we examined the hypothesis that in patients with suspected pre-existing pulmonary oedema caused by mitral valve insufficiency, a colloid priming solution could have beneficial effects on the postoperative accumulation of lung water and gas exchange. To our knowledge, there is no other study available in which the effects of mitral valve replacement on EVLW have been investigated using the convolution technique.

Our results suggest that the postoperative time course of EVLW in patients depends mainly on the preoperative degree of mitral valve failure and not on the type of priming volume. Whereas in patients with MVI-IV° EVLW decreased significantly after surgery, it remained unchanged in patients with MVI-III°, but was still above normal compared with patients undergoing coronary artery bypass surgery.[8] The finding that EVLW values did not completely resolve immediately after surgery might be explained by possible remodelling of the connective tissue of the pulmonary vascular bed, which has been exposed to increased pulmonary pressure and chronic pulmonary oedema over a prolonged time.[23 24] To our knowledge no long-term investigations of EVLW after mitral valve replacement are available. Thus it remains unclear when, if ever, EVLW returns to normal values in these patients; however, we know that during the first 24 h after mitral valve replacement, EVLW is not normal.

Despite increased EVLW, the time to tracheal extubation did not differ between groups or subgroups of patients. As demonstrated by the time course of the Pa_{O_2}/FI_{O_2} ratio, no significant differences occurred despite an increase in EVLW. Therefore, our data suggest that increased EVLW values do not necessarily influence global variables of gas exchange in patients after mitral valve replacement.

In summary, we conclude that the preoperative degree of mitral valve insufficiency was more important for the postoperative time course of EVLW than the type of priming solution. Thus, in contrast with a previous study,[8] we could not demonstrate benefit of a high colloid priming solution with respect to the postoperative time course of EVLW or gas exchange in this group of patients.

Acute normovolaemic haemodilution decreases postoperative allogeneic blood transfusion after total knee replacement

D. OLSFANGER, B. FREDMAN, B. GOLDSTEIN, A. SHAPIRO AND R. JEDEIKIN

Summary

We hypothesized that the success of postoperative blood conservation after acute normovolaemic haemodilution (NVHD) is influenced by the extent of intraoperative bleeding and surgical trauma, and the timing of autologous blood transfusion. As total knee replacement is associated with minimal intraoperative but extensive postoperative blood loss, this procedure is ideally suited to acute NVHD. Therefore, to test our hypothesis, 30 patients undergoing elective total knee replacement were enrolled in a prospective, randomized, controlled study. In groups NVHD-2 and NVHD-6, before induction of anaesthesia patients were bled to a target packed cell volume (PCV) of 28–30%, and in the post-anaesthesia care unit autologous blood was transfused over a 2-h period terminating after operation at 2 and 6 h, respectively. In the control group, NVHD was not performed. After operation, platelets, fibrinogen, prothrombin and partial thromboplastin time, and liver function, urea and electrolytes were measured and compared with preoperative baseline values. Significantly ($P<0.024$) more allogeneic blood was transfused in the control group (21 u.) compared with either group NVHD-2 (7 u.) or group NVHD-6 (5 u.). In the control group, despite the allogeneic blood transfusion, postoperative PCV decreased until day 4 after operation. Coagulation profile, liver function and urea and electrolytes concentrations were unaffected by the method of treatment. We conclude that for total knee replacement, acute NVHD is an effective blood conservation strategy. However, there was no difference in allogeneic blood administration between the two NVHD groups. Coagulation and liver function, and urea and electrolyte concentrations were unaffected by treatment. (*Br. J. Anaesth.* 1997; **79**: 317–321).

Key words
Blood, transfusion. Transfusion, autotransfusion. Blood, haemodilution. Surgery, orthopaedic.

Before administering blood to the surgical patient the sample must be collected, stored and screened for infectious disease and donor–recipient compatibility. This complex process requires a costly organizational infrastructure.

Despite rigorous screening procedures, inadvertent transmission of infectious diseases remains a significant cause of patient morbidity and mortality.[1–7] Furthermore, the increase in life expectancy has adversely affected the ratio of recipients to healthy donors and consequently decreased the availability of allogeneic blood.[8]

In an attempt to conserve natural blood products, curtail financial expenditure, prevent inadvertent transmission of infectious diseases and ensure safe blood transfusion in addition to simplifying the pre-administration process, alternative transfusion methods have been sought. While haemoglobin solutions,[9] perfluorocarbons and liposome-encapsulated haemoglobin have been developed, these compounds are expensive, have a limited circulatory half-life and do not replace the immunological or coagulant functions of natural blood products.[10] Similarly, preoperative autologous blood donation has been shown to be an expensive blood conservation technique.[11 12] Furthermore, because of administrative errors, incompatible blood transfusion may occur.[13 14]

In the surgical context, acute normovolaemic haemodilution (NVHD) is a potentially useful blood conservation strategy.[15] Because autologous blood is ultimately transfused, this simple technique does not require compatibility testing and is not associated with infectious disease transmission. However, as few randomized, prospective, controlled studies have been performed, the efficacy of NVHD in reducing administration of allogeneic blood is the subject of much debate.[16–19]

In our clinical experience, the extent of intraoperative bleeding and surgical trauma, and the timing of autologous blood transfusion directly influence the success of NVHD as a blood conservation strategy. While we have shown that NVHD for scoliosis surgery decreases allogeneic blood requirements both during and after operation,[15] we hypothesize that the extent of intraoperative blood loss during this surgical procedure adversely

influences the success of NVHD as a blood conservation strategy. Unlike scoliosis surgery, total knee replacement is performed with an occlusive tourniquet and is associated with minimal intraoperative but extensive postoperative blood loss. As a result, total knee replacement is ideally suited to evaluate the efficacy of acute NVHD on postoperative blood administration. Therefore, we designed a study to determine the effect of NVHD on postoperative allogeneic blood administration after total knee replacement. In addition, we assessed the optimal transfusion time and effect of NVHD on coagulation factors, liver function, and urea and electrolyte concentrations.

Patients and methods

After obtaining Institutional Review Board approval, we studied 30 healthy, ASA I–III patients undergoing elective total knee replacement in a randomized, prospective, controlled, open label design. Patients with a history of ischaemic heart disease, hypertension, chronic renal failure, liver cirrhosis, bleeding disorders or current anticoagulant therapy were excluded.

On arrival in the operating room holding area, the radial artery was cannulated and monitoring equipment attached. Throughout the perioperative period the following variables were recorded at 1–5-min intervals: intra-arterial pressure, electrocardiogram (ECG) and peripheral haemoglobin oxygen saturation (Sp_{O_2}). Thereafter, according to a randomization table, patients were allocated to one of three groups: in groups NVHD-2 and NVHD-6, while in the operating room holding area patients were bled via a 16-gauge needle placed in the antecubital fossa to a target packed cell volume (PCV) of 28–30% using standard blood collection sets containing citrate–phosphate–glucose with adenine (CPDA-1; Travenol Laboratories Ltd, Israel). PCV was calculated using a Technicon H2 (Bayer) blood analyser. Blood volume was maintained with lactated Ringer's solution in a 1:3 (blood:Ringer's) replacement ratio such that arterial pressure and heart rate remained unchanged. The volume of blood removed was calculated by weighing the collection bag before and after venesection and assuming that 1 mg represented 1 ml of whole blood. All collected autologous blood was stored in the operating room at room temperature. In the control group NVHD was not performed.

On arrival in the operating room, a standardized general anaesthetic technique was used comprising thiopentone 4–6 mg kg^{-1} and fentanyl 5 μg kg^{-1} i.v. for induction and 0.5–1.5% isoflurane (end-tidal) and 70% nitrous oxide in oxygen for maintenance of anaesthesia. Tracheal intubation was facilitated with suxamethonium 1.0 mg kg^{-1} i.v., and surgical relaxation maintained (using a peripheral nerve stimulator) with i.v. pancuronium. After induction of anaesthesia end-tidal carbon dioxide concentration was monitored and the urinary bladder catheterized. Before surgical incision a tourniquet was placed and the operative limb isolated. After placement of the prosthesis, the tourniquet was released and haemostasis performed. Thereafter, the tourniquet was re-inflated until the conclusion of surgery. Intraoperative fluid requirements were administered to maintain heart rate and mean arterial pressure within 20% of baseline values and a urine output of at least 2 ml kg^{-1} h^{-1}. Intraoperative blood loss was assessed by measuring blood volume in suction containers and by weighing all surgical pads and swobs. No blood was administered during operation.

In the post-anaesthesia care unit (PACU) the operative limb was moved using a continuous passive motion device. Autologous blood was reinfused slowly over a 2-h period terminating 2 and 6 h after operation in the NVHD-2 and NVHD-6 groups, respectively. In the control group allogeneic blood was transfused to maintain PCV >28%. On arrival in the PACU and for the duration of hospital admission, subcutaneous heparin 3500 u. was administered three times a day. In the orthopaedic department the decision to transfuse allogeneic blood was taken by an orthopaedic surgeon who was blinded as to the method of treatment. Twenty-four hours after operation the volume of blood in the surgical drain was measured. Thereafter, in order to decrease possible infection, the drain was removed.

Haemoglobin, PCV, prothrombin time (PT), partial thromboplastin time (PTT), platelet count and fibrinogen were measured on arrival in the operating room, after NVHD but before induction, during operation, in the PACU, daily for 9 days and at 3 months after operation. Similarly, serum glucose, sodium, potassium, calcium, urea and creatinine, cholesterol, albumin and bilirubin concentrations were measured at the same times.

Data are expressed as mean (SD or SEM). Descriptive variables were analysed using chi-square tests. Continuous variables were analysed using analysis of variance (with Bonferroni's correction for multiple comparisons). In all cases $P<0.05$ was considered statistically significant.

Results

Patient data (table 1) and duration of anaesthesia and surgery (table 2) were comparable in the three groups. To achieve the target PCV, 1003 (228) and 985 (197) ml of blood were removed over a period of 43 (6) and 41 (4) min in the NVHD-2 and NVHD-6 groups, respectively (table 2). Perioperative crystalloid administration and urine output are presented in table 2. Mean intraoperative surgical blood loss was 370 (78), 353 (63) and 360 (91) ml in the NVHD-2, NVHD-6 and control

Surgery time (min)	201 (23)	188 (35)	183 (19)

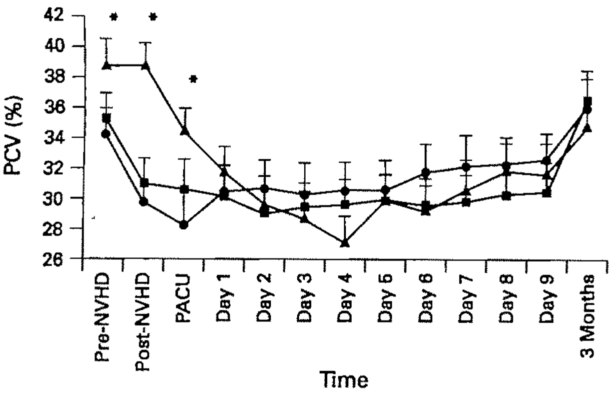

Figure 1 Mean (SEM) perioperative packed cell volume (PCV) in groups NVHD-2 (■), NVHD-6 (●) and in the control group (▲) before and after normovolaemic haemodilution (NVHD), in the post-anaesthesia care unit (PACU) and up to 3 months after operation. *$P<0.05$ compared with groups NVHD-2 and NVHD-6, respectively.

groups, respectively. Twenty-four hours after operation, the volume of blood collected from the surgical drains was 409 (94), 495 (122) and 575 (193) ml in the NVHD-2, NVHD-6 and control groups, respectively.

As a result of the study design, before induction of anaesthesia PCV values in the two NVHD groups were significantly lower than those in the control group. Similarly, on arrival in the PACU a significantly higher PCV was recorded in the control group. During the postoperative period, PCV in the control group decreased, reaching its lowest point on day 4 after operation. However, because of allogeneic blood transfusion, statistical significance was not reached (fig. 1).

In the control group, significantly ($P<0.024$) more allogeneic blood was transfused after operation (table 3). All control patients received allogeneic blood transfusions. A total of 21 u. of packed cells were transfused, with each patient receiving at least 2 u. of blood (table 3). Between days 3 and 6 days after operation, 17 u. of allogeneic blood were transfused. In the NVHD-2 group, six patients received allogeneic blood transfusions and a total of 7 u. of packed cells were administered. Five patients received 1 and one patient received 2 u. of blood. In the NVHD-6 group, five patients received 1 u. of allogeneic blood.

In all patients skin discolouration and swelling caused by subcutaneous haematoma were noted in the ipsilateral dependent thigh and flank.

Preoperative platelet count, PT and PTT were similar in the three groups, and after haemodilution no significant changes were recorded in the NVDH-2 and NVHD-6 groups. Postoperative evaluation of these variables revealed no significant difference between the three groups. Compared with baseline, blood fibrinogen increased significantly in all three groups. While these values remained high until discharge, maximal concentrations were recorded 4 days after operation.

NVDH had no effect on perioperative glucose, calcium, creatinine, urea and electrolytes, cholesterol or bilirubin concentrations. A similar decrease in serum albumin concentration was noted in all groups.

On day 4 after operation, one patient in group NVHD-2 complained of sudden, intense right-sided chest pain which was followed by both circulatory and respiratory arrest. Despite extensive resuscitation the patient died. Because of family preference no post mortem was performed.

Patient follow-up 3 months after operation revealed a PCV of 36.8%, 36.3% and 35.1% in the NVHD-2, NVHD-6 and control groups, respectively. Fibrinogen concentrations measured at this time were similar to preoperative values.

Discussion

The results of this study demonstrated that acute NVHD was an effective blood conservation strategy when performed for total knee replacement. Patients who underwent acute haemodilution required

significantly less postoperative allogeneic blood. In contrast, between days 3 and 6 after operation, nine patients in the control group received allogeneic blood, most receiving at least 2 u.

Analysis of the postoperative PCV data suggests that NVHD directly influenced transfusion requirements and may have effected postoperative blood loss (fig. 1). As expected from the study design, in the immediate postoperative period PCV in the control group was significantly higher compared with groups NVHD-2 and NVHD-6, respectively. After autologous blood transfusion there was no significant difference in postoperative PCV between the three groups. Therefore, as PCV was stable and the allogeneic transfusion greater in the control group, it appears that NVHD may reduce postoperative blood loss.

As postoperative PCV and allogeneic blood requirements were similar in the NVHD-2 and NVHD-6 groups, it appears that the timing of the autologous blood administration did not effect postoperative allogeneic blood requirements. This may be explained by the relatively short time interval between autologous blood transfusion (2 and 6 h after operation). However, autologous blood was kept at the patient's bedside and stored at room temperature. A longer transfusion time interval between groups would have required more elaborate storage and safety facilities and consequently reduced the attractiveness of NVHD as a blood conservation strategy.

In previous studies the use of acute NVHD has been associated with variable results. In a retrospective analysis of patient records Goodnough and colleagues[16] demonstrated only modest blood conservation after acute preoperative NVHD in patients undergoing radical prostatectomy. Furthermore, during surgical correction of scoliosis, retrospective uncontrolled studies demonstrated that 42–66% of patients who underwent NVHD required postoperative allogeneic blood transfusion.[15 20 21] These studies differ from our investigation in both study design and timing of autologous blood transfusion. In previous investigations prospective studies were not performed and the efficacy of NVHD was determined by comparison with historical controls. Furthermore, as both scoliosis surgery and radical prostatectomy are traumatic procedures associated with significant intraoperative blood loss, autologous blood was transfused either during or on completion of the operative procedure. Thus the potential allogeneic blood transfusion-sparing effects of NVHD may have been lost.

We postulate that the postoperative allogeneic blood-sparing effect demonstrated in this study was likely multifactorial. First, Milam and colleagues[22] suggested that in polycythaemic children undergoing cardiac surgery, NVHD results in improved blood flow in the microcirculation and thus decreases coagulopathies and consequent postoperative bleeding. Second, fresh autologous blood is rich in platelets and clotting factors. This together with improved microcirculation may result in decreased postoperative bleeding.[23–26] It is of interest that in our study perioperative PT, PTT, platelets and fibrinogen concentrations were unaffected by the treatment. However, we measured quantitative rather than qualitative function. Furthermore, NVHD may modify the activity of components of the clotting cascade which were not measured. Third, as NVHD decreases PCV, blood with a low red blood cell mass may have been lost into the extravascular compartment. This is supported by the fact that an ipsilateral thigh and flank haematoma was noted in all patients. As intraoperative and 24-h blood loss were similar in the three groups, we suggest that "diluted" blood formed the haematoma in the two haemodilution groups. However, the time of onset and extent of this haematoma were difficult to compare.

In our opinion the sudden death reported in our study was a consequence of the surgical procedure rather than the anaesthetic technique. As the fatal event occurred 4 days after operation and the patient complained of acute right chest pain before cardiorespiratory collapse, we conclude that a massive pulmonary embolism was the likely cause of the patient's death. This theory is supported by the fact that the incidence of deep vein thrombosis and pulmonary embolism after total knee replacement is 40–84% and 1.7%, respectively.[27–29] Unfortunately, a post mortem was not performed.

This study design may be criticized as the trigger to transfuse after discharge from the PACU was based on the orthopaedic surgeon's "transfusion culture" rather than predefined criteria. It is for this reason that the majority of patients in the two NVHD groups received only 1 u. of allogeneic blood. In our opinion patients who required only 1 u. of allogeneic blood were probably transfused inappropriately. If this subset of patients were excluded from statistical analysis the effect of NVHD on postoperative blood requirements would have been even more significant.

We conclude that the efficacy of acute NVHD is likely to be improved in procedures associated with minimal intraoperative but significant postoperative blood loss. Therefore, for total knee replacement, acute haemodilution is a convenient and effective blood conservation strategy. While the exact mechanism of this blood conservation is unclear, to maximize allogeneic blood conservation strict postoperative transfusion criteria must be defined.

Ondansetron compared with metoclopramide in the treatment of established postoperative nausea and vomiting[†]

P. Diemunsch, C. Conseiller, N. Clyti, J. P. Mamet and the French Ondansetron Study Group

Summary

We have studied 746 males and females undergoing general anaesthesia for any type of surgical procedure in a double-blind, controlled, randomized study. After experiencing at least one nausea and/or one emetic episode in the 6 h after recovery from anaesthesia, patients received either ondansetron 4 mg i.v. or metoclopramide 10 mg i.v. Patients were observed for postoperative nausea and vomiting (PONV) for 24 h after drug administration. Complete control of PONV was achieved more frequently in the ondansetron-treated patients compared with the metoclopramide-treated patients during the 24-h period (59% *vs* 41% ($P<0.001$) and 44% *vs* 34% ($P=0.006$) for emetic episodes and nausea, respectively). Furthermore, ondansetron was associated with greater patient satisfaction than metoclopramide ($P<0.001$) with 49% and 32% of patients, respectively, very satisfied. The overall incidence of adverse events was similar in the ondansetron (7%) and metoclopramide (8%) groups. Ondansetron was as well tolerated and more effective than metoclopramide for all assessment criteria in the treatment of established PONV. (*Br. J. Anaesth.* 1997; **79**: 322–326).

Key words
Vomiting, antiemetics. Vomiting, nausea. Vomiting, incidence. Vomiting, nausea, surgical factors.

Postoperative nausea and vomiting (PONV) is a troublesome phenomenon after general anaesthesia. PONV is also a major concern for patients undergoing outpatient surgery under general anaesthesia and may complicate and delay discharge from hospital.[1] In some cases, for example ophthalmic surgery, PONV can compromise surgery.[2]

Ondansetron has been shown to be effective and well tolerated in the prevention and treatment of PONV.[3 4] For prevention, it seems logical to use ondansetron for some procedures known to be associated most commonly with PONV.

In the treatment of established PONV, therapeutic practices differ from one country to another and agents such as metoclopramide and droperidol are often administered. Droperidol has been demonstrated to be effective at low doses but its haemodynamic and sedative effects limit its use, particularly when rapid awakening is sought.[5] Metoclopramide is also used widely as an antiemetic. It was for these reasons that we compared ondansetron with metoclopramide.

In the treatment of established PONV, Claybon[4] compared i.v. ondansetron 1, 4 or 8 mg with placebo in 2812 male and female patients in three different studies. The combined results showed that ondansetron 4 mg was the optimal dose for treating established PONV.

In this study we have compared, under routine clinical conditions, the efficacy and safety of ondansetron 4 mg i.v. with metoclopramide 10 mg i.v. in the treatment of established PONV in patients receiving general anaesthesia.

Patients and methods

This randomised, double-blind, parallel-group comparative study was carried out in 60 French centres. The study was approved by the local Ethics Committee and written informed consent was obtained from each patient.

We studied male and female inpatients, aged 18–75 yr, having undergone surgery under general anaesthesia and scheduled to be hospitalized for at least 30 h after recovery. The main exclusion criteria were patients who had received an antiemetic drug in the 24 h before anaesthesia and during the study, patients who experienced nausea, vomiting, or both, in the 24 h before anaesthesia, and patients who were scheduled to have a nasogastric tube *in situ* after operation. A balanced general anaesthetic technique was used for all patients and the use of propofol was permitted only for induction of anaesthesia.

The following concurrent medications were defined for the purpose of the study: premedication with any benzodiazepine, if required; induction of anaesthesia with i.v. agents such as thiopentone,

[†]Presented in part at the Annual Meeting of the American Society of Anesthesiologists, Atlanta, October 1995.

propofol; analgesia with any i.v. opioid, as required; maintenance of anaesthesia with inhaled nitrous oxide in oxygen and supplemented with halothane, enflurane or isoflurane, as required; neuromuscular block and antagonism with any agent, as required; and postoperative analgesia with opioid or non-opioid analgesics, or combinations of the two, administered parenterally, rectally or orally.

Other concurrent medications (e.g. antibiotics) administered to the patient during the study were also recorded.

Patients who experienced one episode of nausea (duration at least 5 min) or one emetic episode (defined as a single vomit or retch or any number of continuous vomits separated by at least 1 min), or both, during the 6 h after recovery from anaesthesia were allocated randomly to receive either ondansetron 4 mg i.v. or metoclopramide 10 mg i.v. as a slow i.v. injection administered over at least 5 min in a double-blind study (the study drug was administered by a third person, nurse or anaesthetist, who did not participate in the study).

Rescue antiemetic medication was given to patients in case of severe nausea, if an emetic episode occurred at least 15 min after drug administration or at any time at the patient's request. Any licensed antiemetic could be used as rescue medication.

ASSESSMENTS

The number of recurrent emetic episodes during the 15 min to 24 h after the end of drug administration and the time to the first emetic recurrent episode were recorded. The highest nausea grade using a four-point scale (none, mild, moderate, severe) was recorded during the same period. Global satisfaction with the study medication experienced by the patient was assessed using a five-point scale, 24 h after the end of drug administration, as very satisfied, quite satisfied, neither satisfied nor unsatisfied, rather unsatisfied or very unsatisfied. The safety of the study drug was assessed by monitoring adverse events throughout the 24-h period. The investigators recorded any unexpected adverse events, irrespective of their potential relation to the study drug.

All concomitant treatments were recorded over the same period.

STATISTICAL ANALYSIS

The study sample size (n=768) was based on the assumption that complete control of emetic episodes at 24 h would be achieved in 50% of patients in the ondansetron group and in 40% of patients in the metoclopramide group, using a two-sided test with a significance level of 5% and a power of 80%. Nine hundred patients were planned to be included in order to take into account non-evaluable patients. The number of patients took into account the fact that an interim analysis of the primary end-point was planned on the first 450 patients included in the study. Statistical analysis was performed on the intent-to-treat population, that is all patients who were randomized and received medication.

The primary end-point was the proportion of patients experiencing no emetic episode (no retches and/or no vomits) and without rescue or withdrawal during the 15 min to 24 h after drug administration. Patients who were rescued or withdrawn from the study were considered to be treatment failures from that time onwards. Comparisons were made between the two treatment groups using the chi-square test.

Secondary end-points were the number of recurrent emetic episodes, time to first recurrent emetic episode, emesis by gender, incidence and severity of nausea, global satisfaction of the patient, percentage of patients who were rescued, and incidence and severity of adverse events.

Time to first recurrent emetic episode was compared between the two groups using the log-rank test, and associated curves were obtained according to the Kaplan–Meier method. Statistical tests used were either the Wilcoxon rank sum test for the number of emetic episodes, severity of nausea and rescue medication, or the Mantel–Haenszel test for patient global satisfaction. Incidence of nausea was assessed by the two-sided chi-square test.

Patients who received rescue antiemetic medication were regarded as treatment failures. Patients experiencing more than five emetic episodes or who were rescued or withdrawn were assigned the value of five episodes for the purpose of analysis. In addition, rescued patients were assigned a severe nausea grade (data adjusted for rescue).

Results

INTERIM ANALYSIS

Interim analysis of the primary end-point was performed on the first 450 patients (235 ondansetron-treated patients and 215 metoclopramide-treated patients).

Results of the interim analysis showed that the percentage of patients with no emetic episodes and who were not rescued or withdrawn from the study between 15 min and 24 h after drug administration was significantly higher in the ondansetron group than in the metoclopramide group (60% *vs* 42%; P<0.001). It was therefore decided to terminate recruitment into the study at this point and perform the final analysis on all recruited patients. By the time these results were obtained the total number of recruited patients was 746.

FINAL ANALYSIS

A total of 2032 patients who gave written informed consent were screened; 746 of these experienced one episode of nausea or emetic episode, or both, and were allocated randomly to receive ondansetron 4 mg i.v. (n=380) or metoclopramide 10 mg i.v. (n=366). Patient characteristics (table 1), type of surgery performed (table 2), medical conditions and concurrent treatments were well matched in the two groups. However, there was a large proportion of women (91%). The main types of operations performed were gynaecological (52%) and gastro-intestinal (12%). Also, duration of anaesthesia and

Table 1 Patient characteristics (mean (SD or range) or number (%))

	Ondansetron group	Metoclopramide group	Total
No. of randomized patients	380	366	746
Sex (No. (%))

Female	346 (91)	336 (92)	682 (91)
Age (yr)	44 (18–22)	45 (19–74)	45 (18–82)
Weight (kg)	63 (12)	63 (11)	63 (11)

Table 2 Type of surgery performed

	Ondansetron group (n=380)	Metoclopramide group (n=366)	Total
Gynaecological	50%	54%	52%
Gastrointestinal	13%	12%	12%
ENT	10%	10%	10%
Breast	7%	6%	7%
Orthopaedic	6%	6%	6%
Thyroid	6%	7%	6%
Thoracic and cardiovascular	4%	1%	3%
Other	4%	4%	4%

Table 3 Duration of anaesthesia and time to recovery from anaesthesia

	Ondansetron group	Metoclopramide group
Duration of anaesthesia (min)		
Mean	116	121
SD	61	67
Median	105	110
Range	13–375	10–510
Time to recovery from anaesthesia (min)		
Mean	26	25
SD	23	22
Median	20	20
Range	0–230	0–225

time to recovery from anaesthesia were similar in the two groups (table 3).

A similar proportion of patients in both groups received opioid analgesics (176 in the ondansetron group, 159 in the metoclopramide group), non-opioid analgesics (150 in the ondansetron group, 152 in the metoclopramide group) or no analgesics (54 in the ondansetron group, 55 in the metoclopramide group).

Other prognostic factors for emesis were well matched in the two groups, that is previous history of PONV (150 patients in the ondansetron group and 147 in the metoclopramide group), previous history of motion sickness (61 patients in the ondansetron group and 65 in the metoclopramide group), use of propofol (172 patients in the ondansetron group and 168 in the metoclopramide group) and use of atropine (22 patients in the ondansetron group and 26 in the metoclopramide group).

PRIMARY END-POINT

Table 4 Number of emetic episodes recorded between 15 min and 24 h after administration of the study drug. Significance level based on Wilcoxon rank sum test: $P<0.001$

No.of emetic episodes	Ondansetron group (n=380) (No. (%))	Metoclopramide group (n=366) (No. (%))
0	223 (59)	151 (41)
1	34 (9)	32 (9)
2	13 (3)	18 (5)
3	5 (1)	12 (3)
4	4 (1)	6 (2)
≥5	1 (<1)	3 (<1)
Rescued or withdrawn because of treatment failure	100 (26)	144 (39)

The percentage of patients with no emetic episode and who were not rescued or withdrawn from the study between 15 min and 24 h after the end of drug administration was significantly higher in the ondansetron group (59%; 223 of 380) than in the metoclopramide group (41%; 151 of 366) ($P<0.001$; chi-square test).

SECONDARY END-POINTS

Number of emetic episodes

The number of emetic episodes in the ondansetron group was significantly smaller than that in the metoclopramide group ($P<0.001$) (table 4).

Time to first emetic episode

Analysis of the median time to the first emetic episode showed that patients in the ondansetron group remained free of emesis for longer than patients in the metoclopramide group ($P<0.001$) (fig. 1). The median time to the first emetic episode was 5 h in the metoclopramide group compared with more than 24 h in the ondansetron group (59% of ondansetron treated-patients were still free of emesis at 24 h).

Incidence and severity of nausea

The percentage of patients with no nausea adjusted

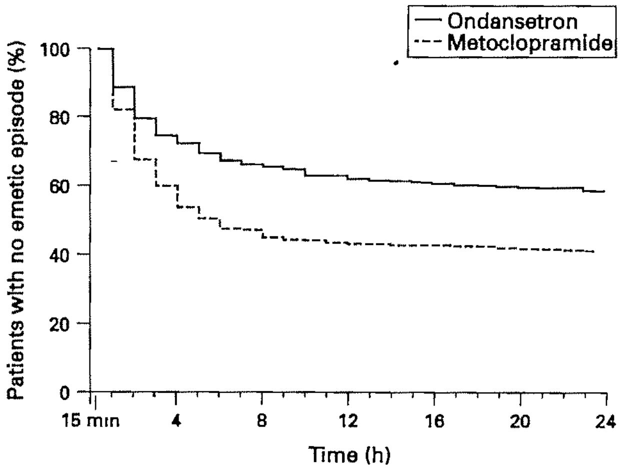

Figure 1 Time to first emetic episode for the period from 15 min to 24 h after drug administration in the ondansetron (n=380) and metoclopramide (n=366) groups.

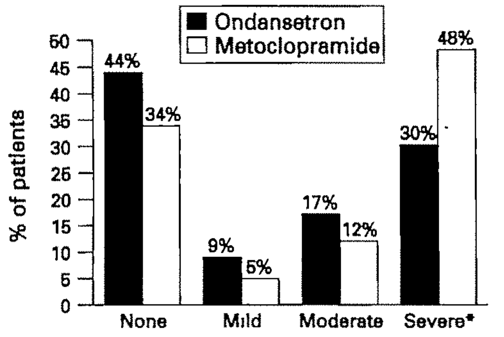

Figure 2 Worst grade of nausea recorded between 15 min and 24 h after drug administration in the ondansetron (n=380) and metoclopramide (n=366) groups. Wilcoxon rank sum test comparing the distribution of nausea grade: P<0.001. (*Rescued patients were assigned a severe nausea grade.)

for rescue between 15 min and 24 h after drug administration was significantly higher in the ondansetron group than in the metoclopramide group (44% *vs* 34%; P=0.006).

Distribution of the worst nausea grade adjusted for rescue between 15 min and 24 h after drug administration was significantly lower in the ondansetron group (P<0.001) (fig. 2).

Global satisfaction of the patient

Distribution of patient global satisfaction was significantly different between the two groups (P<0.001). There were more very satisfied patients in the ondansetron group than in the metoclopramide group (49% *vs* 32%) (fig. 3).

Rescue medication

More patients received rescue medication in the metoclopramide group than in the ondansetron group (39% *vs* 26%; P<0.001).

Safety

A similar proportion of patients experienced adverse events in both treatment groups (ondansetron 7%, metoclopramide 8%). The majority of adverse events were assessed as non-drug-related; 1% of patients in the ondansetron group and 2% of patients in the metoclopramide group experienced a drug-related adverse event. The most frequently reported adverse event was headache, which was assessed as drug-related in four patients (one in the ondansetron group, three in the metoclopramide group). Six patients experienced a serious adverse event during the study; none was assessed as related to study medication.

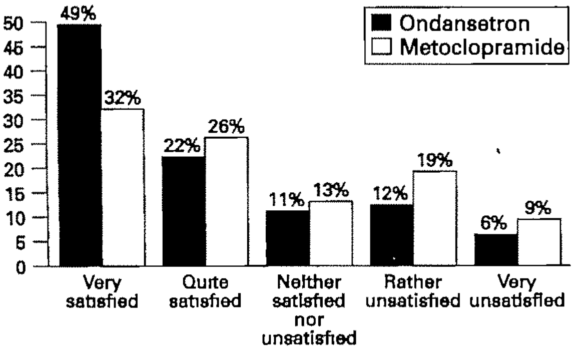

Figure 3 Patient global satisfaction in the ondansetron (n=380) and metoclopramide (n=366) groups. Mantel–Haenszel test comparing the distribution of global satisfaction: P<0.001.

A total of four patients withdrew because of adverse events, none being related to the study treatment.

Discussion

PONV is a common postoperative problem with an overall incidence of approximately 25%.[6] The type of surgery influences the occurrence of PONV: gynaecological surgery is associated with the highest incidence of PONV[7–9] followed by abdominal surgery.[10] Our study population was in accordance with this incidence (746 patients experienced PONV from a total of 2032 patients screened).

A combined analysis of two different studies published by Claybon[4] showed that a single i.v. dose of ondansetron 4 mg was superior to placebo for complete control of emetic episodes (45% *vs* 21%) and complete control of nausea (38% *vs* 20%). Moreover, results of these studies showed that a higher dose of ondansetron (8 mg) had no additional benefit in term of efficacy:safety ratio.

The results of our study showed that ondansetron was significantly superior to metoclopramide for the control of recurrent emetic episodes (59% *vs* 41%; P<0.001) and for the control of nausea (44% *vs* 34%; P=0.006). The median time to the first emetic episode after drug administration was greater than 24 h in the ondansetron group compared with 5 h in the metoclopramide group (P<0.001). Moreover, severity of nausea was less important in the ondansetron group than in the metoclopramide group (P<0.001). Finally, our study evaluated patient global satisfaction which had not previously been routinely investigated in PONV: patients in the ondansetron group reported higher satisfaction scores than those in the metoclopramide group (P<0.001).

Comparative studies in the prevention of PONV showed that ondansetron was superior to metoclopramide[11 12] and droperidol,[13 14] or both.[15 16] Moreover, the reduced requirement for further rescue antiemetics[13 17] may suggest that ondansetron provides greater benefit. Ondansetron has further advantages compared with droperidol: it is not associated with extrapyramidal effects and sedation.[18] Metoclopramide is also known to induce extrapyramidal side effects, especially when used for chemotherapy-induced emesis.[19]

In the treatment of established PONV, there are some data comparing ondansetron with other antiemetics.[4 20 21] These three studies showed that there was no significant difference between ondansetron and droperidol. However, the results could be criticized because of the small study population. In addition, evaluation of patients was followed for only a short period of time after treatment.

To date, this is the largest study comparing ondansetron with an active comparator in the treatment of established PONV. Our results showed that ondansetron was more effective than metoclopramide. The incidence of adverse events was low and similar in both the ondansetron and metoclopramide groups. The majority of adverse events were assessed as non-drug-related. In addition, the nature of adverse events was consistent with previous experience.[3 5 11]

Histological support for the difference between malignant hyperthermia susceptible (MHS), equivocal (MHE) and negative (MHN) muscle biopsies

P. MEZIN, J.-F. PAYEN, J.-L. BOSSON, E. BRAMBILLA AND P. STIEGLITZ

Summary

The aim of this study was to find, using modern techniques, any histological differences in muscle biopsies between malignant hyperthermia (MH) susceptible (MHS), MH equivocal (MHE) and MH negative (MHN) patients. On the basis of the European MH contracture test carried out in 83 patients, 23 were shown to be MHS, nine MHE and 51 MHN. Four lesions were found with a significantly high frequency in MHS and MHE biopsies: muscle fibre hypertrophy and atrophy, internal nuclei and myofibrillar necrosis. These four lesions were observed together in 35% of MHS but in none of the MHE or MHN biopsies. Three of these lesions occurred together in 57% of MHS, 33% of MHE and 4% of MHN biopsies. Our results support a histological difference between MHE, MHS and MHN biopsies and attempt to contribute towards a better definition of MHE status. (*Br. J. Anaesth.* 1997; **79**: 327–331).

Key words
Malignant hyperthermia. Measurement techniques, histology.

Cases of malignant hyperthermia (MH) have been reported since 1960[1] but it was only in 1978 that the first pathological observations on series of muscles from MH susceptible (MHS) patients were described.[2 3]

Studies generally report only a small number of cases; there are few recent data, and histological lesions in MH equivocal (MHE) patients have never been described in comparison with those in MHS patients. Our study included photonic and ultrastructural examination, morphometrical analysis, examining possible immunoglobulin deposits with the use of anti-dystrophin antibodies (in some cases) and statistical analysis.

Patients and methods

The 83 patients studied included 43 females and 40 males of more than 16 yr of age. All patients came from families either found to be or suspected of being sensitive to MH because of an anaesthetic incident. Of the 83 patients, 18 were probands. Their biopsies were performed at least 6 months after the anaesthesic episode. Mean age was 35.3 (range 16–67) yr.

MH SENSITIVITY TEST

Patients underwent biopsy of the vastus medialis muscle under a femoral nerve block with 1% lignocaine injection. The muscle strips were subjected to halothane and caffeine contracture tests. The classification criteria used to differentiate between MHS, MHE and MH negative (MHN) were those of the European protocol.[4]

METHODS

Part of the biopsy was reserved for pathological examination which, for the 83 patients, was carried out by the same pathologist.

The usual colourations and histoenzymatic reactions carried out routinely for diagnosis were performed on the semi-fine sections of frozen material.[5] These allow appreciation of the appearance of the muscle fibres in addition to myofibrillar and mitochondrial functioning.

The search for possible immunoglobulin deposits was carried out under fluorescent light after application of immune serum to IgA, IgG, IgM, C3 and fibrinogen. Anti-dystrophin sera (DYS1, DYS2 and DYS3) were applied to the muscles of MHS patients in which atrophied fibres and necrosis were observed. The presence of dystrophin was revealed by a peroxydase–anti-peroxydase reaction. Ultrafine sections were used for ultrastructural examination after muscle inclusion in epon.

Finally, morphometrical analysis was carried out with the aid of a Biocom image analyser.[6] Type I and II muscle fibres were differentiated by a reaction showing myofibrillar ATPase. Mean diameters were measured using the general histological program Histo 200.

Accepted for publication: April 8, 1997.

STATISTICAL ANALYSIS

A chi-square test was used to establish if the frequency variations of the lesions in the MHS, MHE and MHN muscles were significant. This analysis was completed by a test of linearity designed to evaluate the prevalence of MHS and MHE using the number of lesions observed. The risk of first species ($P=0.05$) was used with the Bonferroni correction for the multiple tests. The relative risks are given within a confidence interval of 0.05 calculated according to the Miettinen formula. The Spierman correlation test was used for studying the relation between contracture strength and either the age of the patient or number of lesions.

Results

PHOTONIC MICROSCOPY EXAMINATION

The most commonly encountered lesions in the muscles of MHS patients under photonic microscopy examination were hypertrophy and atrophy of muscle fibres, internal nuclei and myofibrillar necrosis (fig. 1). The frequency of each lesion was significantly higher in MHS than in MHE and MHN muscles (fig. 2A). The frequency of hypertrophic fibres in the MHE group was significantly different from that in the MHS or MHN group ($P=0.05$). For atrophic fibres, internal nuclei and necrosis, the MHE group was not significantly different from the other two.

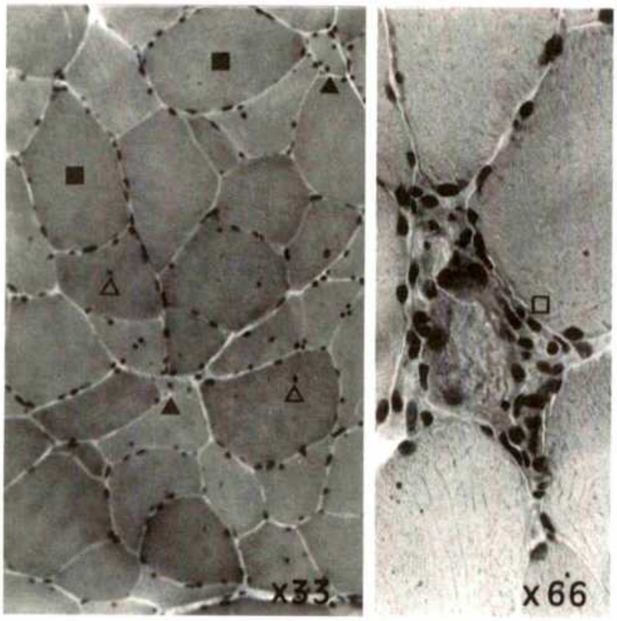

Figure 1 Histological examination. ■=Hypertrophic fibres, ▲=atrophic fibres, △=internal nuclei and □=necrosis.

The four lesions were present in 35% of MHS cases (eight of 23) but did not occur together in MHE or MHN patients ($P<0.0001$). Of the four lesions, three were found together in 57% of MHS cases (13 of 23), in 23% of MHE cases (three of nine) and in 3% (two of 51) of MHN cases ($P<0.001$) (fig. 2B). The test of linearity for empirical frequencies showed that the risk of being MHS was nil if the muscle had either no or only one of these lesions. This risk was multiplied by three if two of these lesions were present, and was multiplied by nine if there were three or four lesions.

The other lesions observed under light microscopy were cores and/or myofibrillary disorganization, segmentation and inflammatory infiltrates. The cores were isolated lesions and were observed either alone or with micro-disruption of the Z material. There were no significant differences in the frequency of these lesions between the three groups.

CONTRACTURE TEST

The force of contracture for 2% halothane was graded from I to V as: 0.2 g<CF<0.3 g=I, 0.3 g<CF<0.5 g=II, 0.5 g<CF<1 g=III, 1 g<CF<2 g=IV, 2 g<CF=V. There was a positive correlation between the force of contraction and the number of lesions (correlation coefficient=0.4) ($P=0.04$).

ANTI-DYSTROPHIN ANTIBODIES

In all MHS cases, muscle fibres showed a regular marking of normal intensity along the sarcolemma membrane.

MORPHOMETRIC ANALYSIS

For each group of patients, mean diameter was calculated for both men and women and for type I and type II fibres. Mean diameters were always

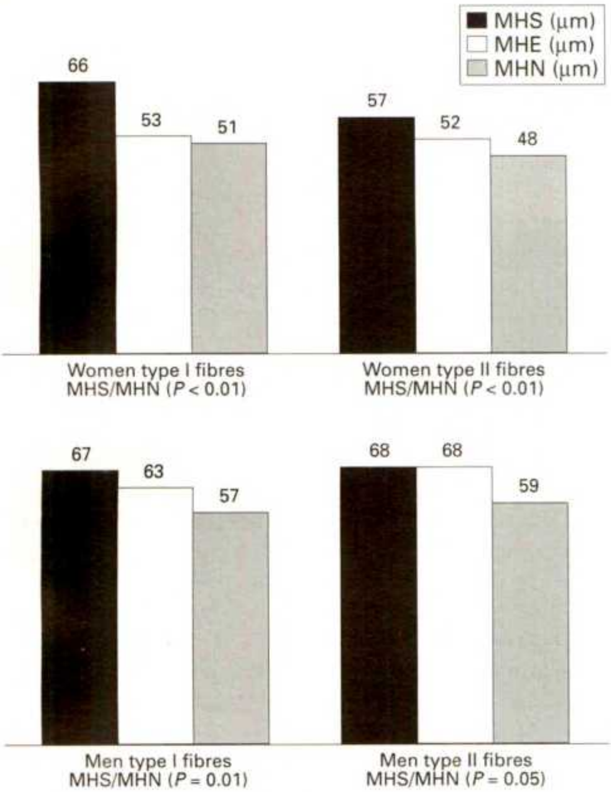

Figure 3 Morphometrical analysis: muscle fibre mean diameters in men and women in the three groups of patients.

higher in MHS than those in MHE or MHN patients (fig. 3).

In MHE, mean diameters of type I and type II fibres were not significantly different from those in MHS and MHN. Conversely, for the two types of fibres and for men and women, mean diameters in MHS were always significantly different from those in MHN.

EXAMINATION UNDER FLUORESCENT LIGHT

Intravascular C3 deposits, linked in one case to IgM deposits, were observed in three MHS patients. Fibrinogen deposits were present in one MHE patient. Four MHN patients had intravascular C3 deposits, which were associated with IgM deposits in two cases. In a fifth MHN patient, only IgM deposits were present. Apparently these deposits were not associated with MH pathology. Their presence was linked to other pathologies specific to the patients and are therefore not discussed.

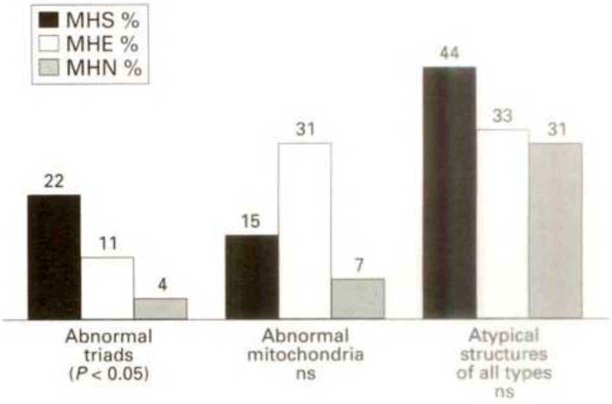

Figure 5 Principal lesions observed under ultrastructural examination in the three groups of patients.

ULTRASTRUCTURAL EXAMINATION

Micro-disruptions of the Z material, invisible under light microscopy, were observed, as were various atypical structures in the muscle fibres. Most frequently, these consisted of L ampula dilatations in triads, but also sarcoplasmic vesicle accumulations, tubular aggregates, spiralated formations and atypical mitochondria (fig. 4). Their frequency is reported in figure 5.

Although relatively uncommon, only the presence of abnormal triads was significantly different in the three groups ($P=0.05$). More precisely, the MHS group was significantly different from the MHN group ($P=0.01$), but the MHE group was not significantly different from the other two.

Finally, the muscle was considered totally free of lesions and atypical structures in 9% of MHS (two of

23), 22% of MHE (two of nine) and 29% of MHN (15 of 51) muscles (ns).

Discussion

Among the 83 patients tested for susceptibility to MH, 23 (28%) had a positive reaction, nine (11%) an equivocal reaction and 51 (61%) were negative. For the MHE population, our results resembled those of Figarella and Pellissier[7] (6%) and those of Krivosic and colleagues[8] (17%).

MH has often been linked to muscular pathologies, the most frequent being central core disease.[9–12] MHS cases have been observed in patients suffering from Duchenne muscular dystrophy,[13] limb girdle dystrophy,[10] glycogen storage disease,[9] congenital myotony,[14] McArdle disease,[15] myotonic dystrophy,[16] congenital muscular dystrophy[17] and mitochondrial myopathy.[18] MHS has also been reported in association with neuropathic diseases (spinal atrophy or neuropathy[19]) or with various pathologies such as diabetus mellitus[9] or sudden death of the newborn.[10]

The 83 patients in our study were clinically healthy and histological examination did not reveal any specific pathology. In particular, no patient had a mitochondrial myopathy, apparent as ragged red fibres and negative fibres with cytochrome oxydase reaction, as reported by Figarella and Pellissier.[7] Conversely, in common with Isaacs,[3] we observed under photonic or electronic microscopy, abnormal mitochondria in 15% of MHS, 31% of MHE and 7% of MHN biopsies. However, the lesions were disseminated in muscle fibres, were not numerous and were therefore not significant.

The lesions observed most frequently under light microscopy were hypertrophy and atrophy of muscular fibres, internal nuclei and myofibrillar necrosis; some have been described by Harriman and colleagues[2] and by Isaacs[3] since 1978. The most frequent lesion was hypertrophic fibres, found in 87% of MHS and 56% of MHE cases. Curiously, Harriman did not report this lesion in 1987[20] and observed it rarely in 1988 [21] but his study was only qualitative. The hypertrophy we observed was confirmed by morphometric analysis. Mean diameters of muscle fibres were higher in MHS than in MHE or MHN patients, taking into account fibre type and patient sex. This observation confirms those of Harden-Mayor and colleagues,[22] Bergeson and colleagues[23] and Krivosic and colleagues[8] who, in common with us, observed no abnormalities in the distribution of the two fibre types.

These authors agreed on the observation of atrophic fibres. Ellis[24] also described them as the only morphometric abnormality. We observed atrophic fibres much more frequently in muscles of MHS and MHE patients than in MHN patients. They were angular in a large number of cases but their disseminated arrangement and absence of grouping by fibre type does not support an association with a neurogenic pathology.[19]

Internal nuclei were much more numerous in MHS (56% of cases) than in MHE (22%) or MHN (4%) biopsies. Harden-Mayor and colleagues[22] observed them in 49% of MHS cases and Harriman and colleagues[2] in more than 25% of fibres of MHS subjects. Conversely, Rieske-Nielsen[16] described an increase in the total number of nuclei and Figarella and Pellissier[7] observed no difference. This disparity may be a result of the great variety of anomalies that can be observed from one patient to another or from one family to another.

Lesions of necrosis or myophagy, or both, were far more numerous in MHS (44%) than in MHE (11%) and MHN (4%) biopsies. Necrosis, linked to the presence of atrophic and hypertrophic fibres, prompted us to apply anti-dystrophin antibodies in an attempt to detect Duchenne or Becker muscular dystrophy. We found regular marking of muscular fibres in all cases and therefore abandoned this diagnostic hypothesis.

Depending on the lesion studied, the MHE group either is or is not significantly different from the MHS group or from the MHN group.

The combined presence of the four lesions (hypertrophy, atrophy, internal nuclei and necrosis) is particularly interesting. This was observed in 35% of MHS subjects but not in MHE or MHN subjects. Moreover, three of the four lesions were found together in 57% of MHS, in 33% of MHE and in only 4% of MHN biopsies. Only one other study[8] reported a link between morphometrical and morphological lesions; these authors found 1.8 alterations per case in the group of MHS and MHE patients, and only 0.5 alterations per case in the MHN group.

Statistical analysis showed that the concomitant presence of these four lesions was not a result of chance and that there were significant differences between the three groups. As the number of associations of these abnormalities increased, so did the risk that a patient was MHE or MHS. On the other hand, we observed no significant relation between the age of the patients and the presence of 1–4 lesions in their biopsies. However, in the MNH population, the atrophic fibres were slightly more numerous in older patients. Moreover, we observed no difference in the number of lesions in MH probands, non-MH probands and other patients, or in the number of lesions and the severity of the MH episode in these patients. However, the number of these lesions was correlated to contracture strength in the *in vitro* contracture test.

Under ultrastructural examination we observed atypical structures in muscle fibres, more numerous in MHS than in MHE or MHN. Particular attention was paid to examination of atypical triads, showing dilatations of the sarcoplasmic reticulum cisternae. They were more numerous in MHS (22%) than in MHE (11%) or MHN (4%). Only one author,[16] reported the presence of abnormal triads in three of 10 probands. The rarity of this observation is surely because ultrastructural studies are rare and, when they are carried out, only take into account a small number of patients. Yet, the number of cases in which we observed abnormal triads was low considering the fact that MH crisis is probably linked to an anomaly in the release of calcium at the triad site.

Finally, we considered the muscle to be totally free of lesions in 9% of MHS, 22% of MHE and 29% of MHN cases. These results were statistically significant but very different from those of Harriman[20] who found normal muscle in 70% of MHS subjects. However, our results are closer to those of Figarella and Pellissier[7] (26%) and Stathousers[25] (23%) but these authors did not carry out morphometrical analysis and, despite having studied a large number of cases, ultrastructural examination was performed only in exceptional cases.

In summary, the lesions we observed most frequently in MHS and MHE muscle biopsies were hypertrophy, atrophy, necrosis of fibres and internal nuclei. Their combined occurrence allowed us to distinguish significantly between the muscles of MHS, MHE and MHN patients.

In general and taking all lesions into account, we observed a linear effect for their increase in the three categories of patients: MHN, MHE and MHS. The equivocal group was situated between the two others and was either significantly different or not depending on the lesions concerned.

A correlation was observed between the histopathological appearance of the muscles and their reactivity to the contracture test and, if morphological observation alone does not make it possible to diagnose susceptibility or an equivocal reaction to MH, it does provide a good probability index.

Detection of a novel mutation at amino acid position 614 in the ryanodine receptor in malignant hyperthermia

K. A. QUANE, H. ORDING, K. E. KEATING, B. M. MANNING, R. HEINE, D. BENDIXEN, K. BERG, R. KRIVOSIC-HORBER, F. LEHMANN-HORN, T. FAGERLUND AND T. V. MCCARTHY

Summary

Malignant hyperthermia (MH) is a potentially fatal autosomal dominant disorder of skeletal muscle and is triggered in susceptible people by all commonly used inhalation anaesthetics and depolarizing neuromuscular blocking agents. To date, eight mutations in the skeletal muscle ryanodine receptor gene (RYR1) have been identified in malignant hyperthermia susceptible (MHS) and central core disease (CCD) cases. We have screened the RYR1 gene in affected individuals for novel MHS mutations by single stranded conformational polymorphism (SSCP) analysis and have identified a G to T transition mutation which results in the replacement of a conserved arginine (Arg) at position 614 with a leucine (Leu). The Arg614Leu mutation was present in three unrelated MHS individuals of 151 investigated. The mutation was not detected in 148 normal chromosomes and segregated precisely with MHS in family members from one of the probands where DNA was available for analysis. This mutation occurs at the same position as the previously identified Arg to Cys mutation reported in all cases of porcine MH and in approximately 5% of human MH. A comparison of the phenotypes of the Arg614Leu and Arg614Cys probands is presented. (*Br. J. Anaesth.* 1997; **79**: 332–337).

Key words
Malignant hyperthermia. Genetic factors, hyperthermia. Receptors, ryanodine.

Malignant hyperthermia (MH) is a clinically heterogeneous autosomal dominant disorder elicited in susceptible individuals by widely used volatile anaesthetics and depolarizing neuromuscular blocking agents and characterised by skeletal muscle hypermetabolism.[1 2] The reported incidence of MH ranges from approximately 1 per 10 000 to 1 per 50 000 anaesthetics with an apparently higher incidence in children.[3]

MH also occurs in pigs and is closely associated with muscle hypertrophy. Biochemical studies on porcine MH indicate that the primary defect in MH susceptible (MHS) cases is in the skeletal muscle calcium release channel, commonly termed the ryanodine receptor (RYR1).[4] Sequence analysis of the porcine RYR1 gene has shown that a point mutation is present in MH pigs that results in an arginine (Arg) to cysteine (Cys) substitution at position 615 (Arg615Cys).[5] A mutation equivalent to the pig Arg615Cys has also been found in human MH.[6] The human mutation is known as the Arg614Cys mutation and results from a C1840T transition mutation.

In addition to this mutation, another seven RYR1 point mutations have been identified in MHS and central core disease (CCD)[7] pedigrees, namely Arg163Cys,[8] Gly248Arg,[9] Gly341Arg,[10] Ile403Met,[8] Tyr522Ser,[11] Gly2433Arg[12 13] and Arg2434His.[14] Collectively, these mutations have been found in approximately 10% of Caucasian MHS cases. Identification of these mutations firmly establishes the RYR1 gene as a susceptibility gene in MH and indicates that mutations are likely to be present in the RYR1 gene in all RYR1 linked families.

In an effort to identify new mutations in the RYR1 gene causing MH we have undertaken systematic screening of the 15 099 bp coding sequence of the RYR1 gene in unrelated MHS individuals for mutations. We describe the identification of a novel Arg614Leu mutation which we detected in a MHS pedigree and two unrelated MH probands.

Patients and methods

Screening for single nucleotide changes in the RYR1 gene of MHS patients requires amplification of the entire gene from each individual in short segments and subsequent investigation of each of these gene segments for nucleotide changes. The RYR1 gene spans 158 kb of genomic DNA and contains more than 100 exons.[15] For amplification purposes, we chose to use RYR1 complementary DNA (cDNA) as muscle biopsy material was available from MHS individuals. For synthesis of cDNA, total RNA was first extracted by guanidinium thiocyanate[16] from the muscle tissue and first strand cDNA synthesis was performed as described previously.[10] PCR primers were designed using the computer programme OLIGO version 4.0,[17] so that the entire 15 099 bp coding sequence of the RYR1 gene[18] could be amplified in short (200–450 bp) overlapping segments, using cDNA as template in the amplification reaction (the sequence of the 64 PCR primer pairs and PCR conditions are available on request).

Screening for single nucleotide changes in RYR1 segments amplified by PCR from the MHS patients was performed using the well established single stranded conformation polymorphism (SSCP) method[19] under three different electrophoretic conditions, as described previously.[10] The DNA bands on the polyacrylamide gel were detected by autoradiography. Normal samples were included in the SSCP analysis as controls to allow identification of normal alleles.

Sequence analysis of PCR amplified fragments exhibiting aberrant SSCP patterns was performed as described previously.[10]

For segregation studies, genomic DNA was extracted from peripheral blood as described previously.[20] A 74-bp fragment spanning the G1841T mutation of the RYR1 gene was amplified from genomic DNA using PCR, as described previously.[6] For SSCP detection, the samples were run on a 6% polyacrylamide gel (acrylamide N, N'methylenebisacrylamide=99:1) with 5% glycerol at room temperature for 1.5 h. The G1841T SSCP was detected by autoradiography.

For the investigations reported here, muscle samples were obtained from 29 MHS patients and five MH negative (MHN) individuals through the Lille, Copenhagen and Ulm MH testing centres. Patients were tested for MH susceptibility using the standardized European Malignant Hyperthermia Group IVCT procedure.[21]

Results

SSCP ANALYSIS OF THE RYR1 GENE IN MH

SSCP polyacrylamide gel band patterns, which did not correspond to those observed in normal individuals, were detected in eight areas of the RYR1 gene in patient 12F. Seven of these were considered to be polymorphisms (normal variations in the DNA sequence which do not result in an abnormal protein product[9 14]) as they were present in some of the control samples (normal individuals) and/or were found to be silent mutations after DNA sequence analysis. However, direct sequencing of the RYR1 segment 1727–1993 in patient 12F, which also demonstrated an aberrant SSCP pattern, revealed the presence of the single base substitution G1841T which results in the replacement of an Arg with a Leu at position 614 (fig. 1).

The presence of the G1841T missense mutation in genomic DNA extracted from blood samples was verified by checking the appropriate amplified products for the presence of the SSCP banding pattern characteristic of the presence of the mutation and by direct sequencing.

To establish if the Arg614Leu mutation was present in the normal population, 148 normal chromosomes were examined for the presence of the mutation. None displayed the candidate mutation. In order to determine if these mutations were present in the RYR1 gene of other MHS pedigrees or CCD pedigrees, 122 additional

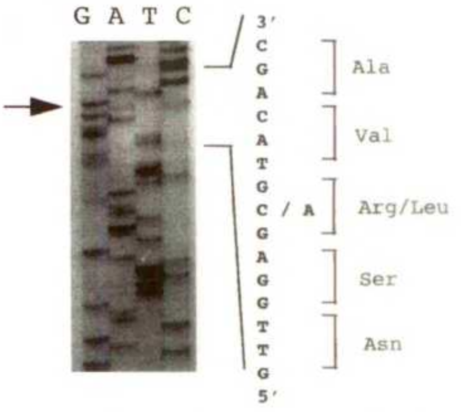

Figure 1 Nucleotide sequence of the mutated region in RYR1 1727–1993 segment from patient 12F. Sequencing was carried out using alpha-32P dCTP and was performed with the reverse primer 1993 so that the sequence of the reverse strand was obtained. The position of the C1841A transition on the reverse strand sequence (G1841T on the forward strand) is indicated by the arrow.

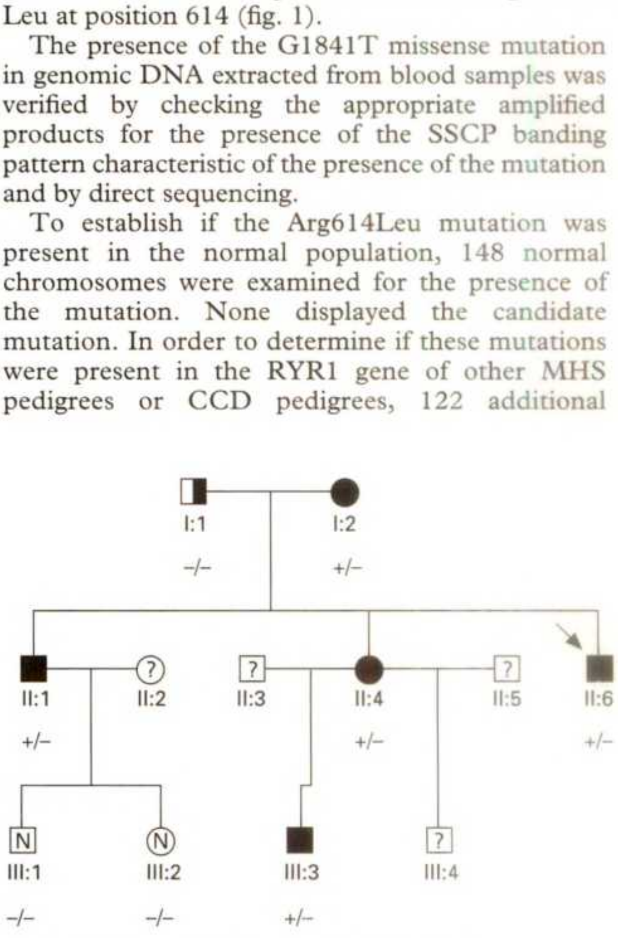

Figure 2 Pedigree of MH proband D15. Symbols: black=MHS; open=MHN; half-black=MHE(h); open with question mark=disease status unknown. The proband (individual II-6) is indicated by an arrow. Segregation of the Arg614Leu RYR1 mutation is also indicated: + =presence of the mutant allele; − =presence of the normal allele.

Table 1 Results of the *in vitro* contracture test in (A) individuals with the Arg614Leu mutation, including members of pedigree D15 and (B) probands with the Arg614Cys mutation. The halothane and caffeine thresholds are the concentrations of halothane (%) and caffeine (mmol litre^{-1}), respectively, at which a contracture of 0.2 g tension is generated. *Taken from.[22] NA=not available

unrelated MHS and five unrelated CCD patients were investigated for the presence of these mutations. The mutation was detected in one Danish (D15) and one German (GR1) MHS patient.

The family of individual D15 (fig. 2) was investigated to determine if the Arg614Leu mutation co-segregated with the MHS phenotype. The mutation co-segregated with the MHS phenotype in this family (fig. 2). The families of individuals 12F and GR1 were unavailable for analysis.

Interestingly, Arg614 is the position of the original porcine RYR1 mutation (Arg615Cys and Arg614Cys in pigs and humans, respectively) which accounts for all cases of porcine MH investigated to date and for approximately 5% of human MH cases.[6] As Arg614 is the position of two MH causative mutations, it is of interest to compare the contracture data and clinical phenotypes. Table 1 presents the IVCT results of individuals carrying the Arg614Leu mutation (pedigree of D15, 1GR, 12F) and results of individuals carrying the Arg614Cys mutation, including six MH probands and five individuals from pedigree MH011 described by Deufel and colleagues.[22] Individual 408 of the MH011 pedigree is homozygous for the Arg614Cys mutation although the two C1840T base transitions segregate independently. Individual 506 who is heterozygous for the Arg614Cys mutation was diagnosed MHN by the IVCT and is the only reported MHN individual carrying the Arg614Cys mutation.[22]

The contracture thresholds (the concentration of caffeine or halothane at which a contracture of 0.2 g tension is generated) of the three probands with the Arg614Leu mutation varied significantly for caffeine (0.5–1.5 mmol litre^{-1}) whereas the halothane threshold was the same in all three cases (0.5%)

(table 1). Individual 506 of pedigree MH011, who is MHN and heterozygous for the Arg614Cys mutation, registered a caffeine threshold >4.0 mmol litre^{-1} and a halothane threshold >3.0%. The contracture thresholds of MHS individuals with the Arg614Cys mutation ranged from 0.5 to 2.0 mmol litre^{-1} for caffeine and from <0.5% to 2.0% for halothane.

In an effort to compare the clinical phenotype of MHS individuals with the Arg614Cys and Arg614Leu mutations, we applied the MH clinical grading scale devised by Larach and colleagues[23] (table 2). In this system, the quantitative likelihood that an adverse anaesthetic event represents MH is based on points assigned to specific abnormal signs and laboratory findings (clinical indicators) observed during an acute anaesthetic reaction. Points are assigned for each indicator present. As several agreed upon indicators are the manifestations of the same process, only the single indicator with the highest score within a given process would count towards the raw score. These points are then summed to produce a raw score that an adverse anaesthetic reaction is a MH event.

Discussion

In an ongoing effort to identify new mutations in the RYR1 gene causing MHS, we have investigated the RYR1 gene in unrelated MHS patients for the presence of new mutations. Analysis of the RYR1 cDNA sequence was performed in preference to analysis of the genomic DNA sequence (>100 exons) as only 64 PCR primer pairs are required for the former while more than 100 primer pairs are required for the latter.[15] Furthermore, as muscle biopsy samples from MHS individuals are readily available after the IVCT, availability of RNA for cDNA synthesis is not a limiting factor. The RYR1 PCR primers described here work reproducibly to give good quality PCR products suitable for SSCP analysis and DNA sequencing.

In this study, we detected a novel Arg614Leu mutation in three of 151 unrelated Caucasian MHS probands. The pedigree of one of these probands was available for analysis and the Arg614Leu mutation segregated with MHS in this pedigree (fig. 2). Individual I-1 of this pedigree, diagnosed as MHE(h) by the IVCT, was negative for the presence of the mutation. Examination of the contracture records showed that this individual exhibited a significant response to halothane (0.4 g at 2% halothane). The observation that some patients can produce significant responses in the IVCT in the absence of the reported segregating mutation has been reported previously by us in families where the Gly341Arg and Gly2433Arg mutations segregated with MHS.[10 12]

The Arg614Leu mutation was not detected in 148 normal chromosomes. Furthermore, examination of the RYR1 genes sequenced to date[5 17] and related isoforms[24–27] indicate that Arg614 is a functionally important amino acid in the RYR proteins as it is conserved across species (fig. 3). Therefore, the Arg614Leu mutation is not likely to be a coincidental polymorphism and is likely to cause MHS in patients bearing the mutation.

The Arg614Cys and Arg614Leu mutations are the result of a C1840T and G1841T transition, respectively, at a CpG dinucleotide in the RYR1 gene sequence. Methylation of a CpG dinucleotide to 5-methyl cytosine creates a mutation hot spot because of the high frequency of deamination of 5-methyl cytosine to thymidine, resulting in the TpG dinucleotide and the complementary dinucleotide CpA.[28] CpG dinucleotides are the site of approximately 35% of all known disease causing point mutations and of these, more than 90% are accounted for by C to T or G to A transitions.[29] In contrast, the Arg614Leu mutation is the result of a G1841T transition at this CpG dinucleotide.

As Arg614 is the position of two mutations potentially causative of MH, we compared the contracture data and clinical phenotypes of probands (tables 1 and 2). Comparison of the caffeine and halothane contracture thresholds (the concentrations at which a contracture of 0.2 g tension is generated) of individuals carrying the Arg614Leu and Arg614Cys mutations (table 1) suggests that the Arg614Leu mutation exhibits a more severe phenotype in the IVCT.

Mutations in the RYR1 gene that cause MH are thought to make the Ca^{2+} release channel sensitive to lower concentrations of agonists.[30] This hypersensitive gating of the channel enhances rates of Ca^{2+} release from the sarcoplasmic reticulum during anaesthesia which results in sustained muscle contraction and sustained glycolytic and aerobic metabolism associated with MH.[30] The suggestion of a more potent effect of the Arg614Leu mutation compared with the Arg614Cys mutation in the IVCT could be explained by increased sensitivity of the RYR1 protein with the Arg614Leu mutation to

stimulators of channel opening such as halothane and caffeine. However, the sample number of this study was small and a larger sample size is necessary to verify this observation.

The clinical details of MHS probands carrying the Arg614Leu and Arg614Cys mutations are presented in table 2. The MH clinical grading scale devised by Larach and colleagues[23] was applied to each individual. As all the clinical indicators (clinical signs and laboratory tests) were not recorded or performed in each case during the anaesthetic reaction, direct comparison of the MH raw scores of probands was not possible (table 2). In addition, early diagnosis of an MH episode followed by prompt treatment implies that many of the clinical signs of an MH episode do not occur and a low raw score would thus result. This severely restricts the usefulness of the clinical grading scale for phenotype–genotype correlation studies. As seen in table 2, the phenotype of both the Arg614Leu and Arg614Cys mutations is variable: the presence of several clinical signs of the MH episode, such as muscular rigidity, respiratory acidosis, temperature increase.

Detection of the Arg614Leu mutation brings to nine the total number of RYR1 mutations reported to date in MHS/CCD pedigrees. These mutations cluster in two regions of the protein: seven mutations in the amino terminal region (residues Arg163 to Arg614) and two mutations near the centre of the protein (Gly2433 and Arg2434). Arg614 is the first amino acid of the RYR1 protein where two potentially causative mutations for MH are described.

Acknowledgements

This work was supported by grants from the Wellcome Trust Fund (038165/1/1.5/AH) and the Irish Health Research Board.

Since submission of this manuscript, two additional mutations in the RYR1 gene have been reported in MH.[31 32]

Changes in inflammatory mediators during orthotopic liver transplantation

M. C. BELLAMY, H. F. GALLEY AND N. R. WEBSTER

Summary

Transplantation is associated with an inflammatory rejection response. Graft reperfusion causes typical haemodynamic and biochemical responses. In this study we have investigated the relationship between these haemodynamic responses and changes in circulating inflammatory mediators after graft reperfusion in 10 consecutive patients undergoing orthotopic liver transplantation. After reperfusion, systemic vascular resistance index decreased (P=0.011) and cardiac index increased (P=0.038). These characteristic haemodynamic changes of the reperfusion syndrome were accompanied by global increases in cytokine concentrations. Plasma concentrations of leukotrienes decreased, while thromboxane B_2 and platelet activating factor remained increased throughout. Reperfusion-mediated changes in inflammatory mediators may account for the haemodynamic disturbance. (*Br. J. Anaesth.* 1997; **79**: 338–341).

Key Words
Liver, transplantation. Polypeptides, cytokines. Immune response.

Liver transplantation is associated with a complex sequence of events, including immune activation, haemodynamic derangement and long-term immune rejection reactions. Reperfusion injury, thought to be a result of increased oxygen derived free radical release and characterized by loss of endothelial cell viability, occurs after cold ischaemic storage and subsequent reperfusion.[1–4] Deranged endothelial cell function may in turn result in leucocyte activation and release of inflammatory mediators which may then cause graft damage and rejection. While preservation injury of the graft may result from activation of Kupffer cells and consequent local injury,[5] our study was concerned with the host systemic response to graft reperfusion.

Extra-hepatic effects of hepatic reperfusion result in haemodynamic deterioration and biochemical responses similar to those seen in sepsis. The causes of this response are poorly defined; animal models of ischaemia–reperfusion syndrome have demonstrated increased expression of tumour necrosis factor-α (TNFα).[6] In these models, TNFα and haemodynamic changes resemble those seen in sepsis, where release of TNFα and a range of interleukins (IL) are associated with reduction in systemic vascular resistance and an increased cardiac index.[7] Moreover, cytokines are involved in rejection reactions which are a complication of liver transplantation.[8 9] Thus ischaemia–reperfusion syndrome is likely to have several important intra- and extra-hepatic effects on outcome. The mechanisms underlying reperfusion syndrome have not been elucidated. We have therefore examined changes in cytokines and arachidonic acid metabolites after reperfusion to investigate the relationship between inflammatory and haemodynamic responses.

Patients and methods

Approval for the study was obtained from the local Clinical Research (Ethics) Committee. We studied 10 consecutive adult patients undergoing elective orthotopic liver transplantation after obtaining written informed consent.

Peripheral venous and radial artery cannulae were inserted and anaesthesia was induced with alfentanil 0.1 mg kg^{-1} and midazolam 0.1 mg kg^{-1}. Neuromuscular block was facilitated by a bolus dose of atracurium 0.5 mg kg^{-1} followed by an infusion of 0.4 mg $kg^{-1} h^{-1}$. After tracheal intubation, the lungs were ventilated to normocapnia with oxygen-enriched air and 1 MAC of isoflurane. Anaesthesia was supplemented with an infusion of alfentanil 0.1 mg $kg^{-1} h^{-1}$. A central venous cannula, pulmonary artery catheter and 18-F percutaneous cardiac bypass catheter were inserted according to our usual practice.[10] Dopamine was infused throughout the procedure at a rate of 3 μg $kg^{-1} min^{-1}$. All patients were established on veno-venous bypass at the beginning of the anhepatic phase, at a flow rate of 0.4×cardiac output to help maintain haemodynamic stability.[11] Tranexamic acid 1 g was administered prophylactically, followed by an infusion of 300 mg h^{-1} until the end of surgery.[12] After excision of the liver and before reimplantation, prednisolone 10 mg kg^{-1} was administered. Where necessary, adrenaline was given in incremental boluses of 50 μg to maintain haemodynamic stability at reperfusion.

Serum potassium concentration was maintained

Table 1 Changes in inflammatory mediators following graft reperfusion. Data are median (range) and were compared using Wilcoxon signed rank test

	Time III_{-5} (pg ml^{-1})	Time III_{60} (pg ml^{-1})	*P*
Tumour necrosis factor-α	4.4 (4.4–12)	32 (14–154)	0.008
Tumour necrosis factor receptor 1	3033 (2437–5621)	8108 (5783–21940)	0.008
Interleukin-1β	1.0 (1.0–1.3)	1.5 (1.0–15.0)	0.04
Interleukin-1 receptor antagonist	1324 (220–10010)	5467 (653–24660)	0.06
Interleukin-6	376 (82–2855)	2137 (272–24660)	0.02
Interleukin-8	121 (50–338)	743 (398–1575)	0 04
Platelet activating factor	978 (741–2577)	1096 (453–1853)	ns
Thromboxane B_2	330 (120–620)	370 (120–900)	ns
Leukotriene C_4, D_4, E_4	800 (110–6800)	580 (40–1200)	ns

in the range 4.0–5.0 mmol litre^{-1} and ionized calcium in the range 0.8–1.4 mmol litre^{-1}. Blood and colloid (modified fluid gelatin) were infused at 37 °C via a rapid infusion system to maintain the packed cell volume at 0.26–0.32 and central venous pressure at 6–12 mm Hg.

Cardiac output was measured by the triplicate thermodilution method, and cardiac index and systemic vascular resistance index (SVRI) were calculated 5 min before (III_{-5}), and 5, 10, 20, 30 and 60 min (III_5, III_{10}, III_{20}, III_{30} and III_{60}) after graft reperfusion. Blood samples (5 ml) were collected at III_{-5} and III_{60} into plain tubes for assay of cytokines, and into EDTA tubes containing 30 μl of indomethacin 0.04 mol litre^{-1} for measurement of leukotriene and thromboxane. These were centrifuged immediately and stored at −70 °C until assay. Samples were obtained at the same times for assay of platelet activating factor (PAF) and were treated as follows: 2 ml of blood were added immediately to 6 ml of ice-cold methanol and vortex mixed. After centrifugation at 3000 *g* for 20 min, the supernatant was frozen at −70 °C until assay. Enzyme-linked immunoassay was used to measure TNFα, IL-1β, IL-6 and IL-8. Thromboxane B_2, total leukotrienes (LTC_4, D_4 and E_4), TNF receptor 1, IL-1 receptor antagonist (IL-1ra) and PAF were measured using radioimmunoassay. Samples from single patients were assayed in the same batch, and all assays were carried out within 1 month.

STATISTICAL METHODS

Data are expressed as median (range). Changes in cardiac index and SVRI with time were analysed using Friedman analysis of variance. Friedman is a non-parametric approach based on rank. We chose this approach because our numbers were small, and to protect against potential effects of individual "rogue" values. The difference between pre- and post-reperfusion biochemical data was examined using Wilcoxon signed rank test. All statistical tests were performed using SPSS for Windows (v 6.0). Changes were taken to be statistically significant when $P<0.05$.

Results

One patient died during operation, and data from nine patients (five women, median age 49 (range 39–62) yr) are therefore presented. Their diagnoses were primary sclerosing cholangitis (three patients), chronic rejection after previous transplantation (two),

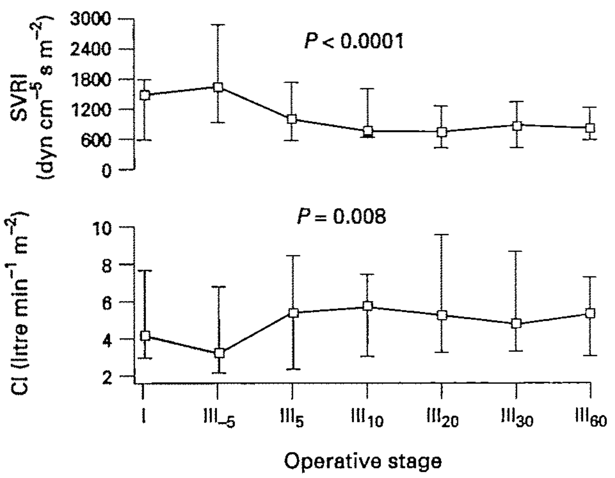

Figure 1 Time course of haemodynamic changes (systemic vascular resistance index (SVRI) and cardiac index (CI)) during orthotopic liver transplantation in nine subjects. Results are shown as median (range) and were analysed using Friedman two-way analysis of variance.

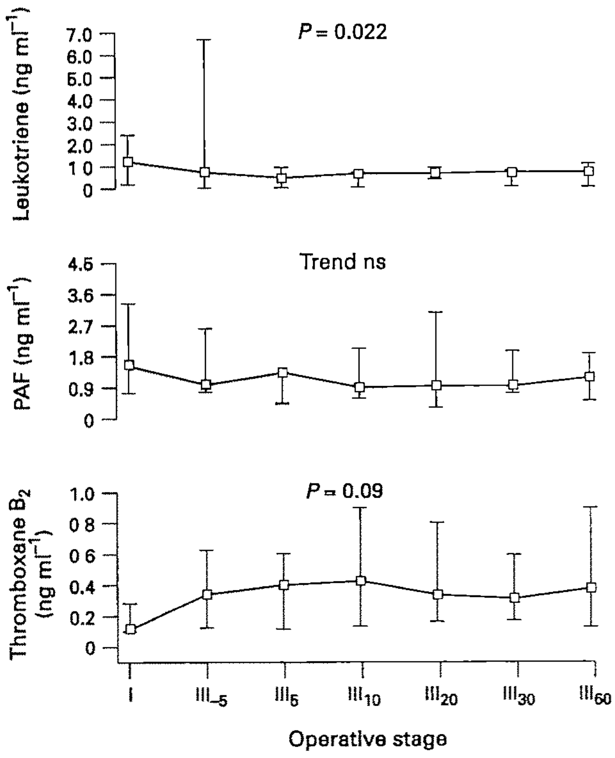

Figure 2 Time course of inflammatory mediator changes during orthotopic liver transplantation in nine subjects. Results are shown as median (range) and were analysed using Friedman two-way analysis of variance.

chronic active hepatitis, sero-negative viral hepatitis, alcoholic cirrhosis and haemochromatosis (one each).

There were significant changes in both cardiac index (P=0.008) and SVRI (P<0.0001) (Friedman) during transplant (fig. 1). Cardiac index increased from 3.3 (2.2–6.8) litre min^{-1} m^{-2} at III_{-5} to 5.4 (2.3–8.4) litre min^{-1} m^{-2} at III_5 (P=0.038, Wilcoxon). SVRI decreased on reperfusion of the liver graft from 1647 (930–2871) dyn s^{-1} cm^{-5} m^{-2} to 883 (561–1727) dyn s^{-1} cm^{-5} m^{-2} (P=0.011).

Concentrations of all cytokines and IL-1ra and TNF receptor 1 increased at III_{60} compared with III_{-5} (table 1). Total leukotriene concentrations showed a decreasing trend with time (fig. 2). The increased leukotriene concentrations seen at III_5 related to a single outlying value. Thromboxane B_2 and PAF concentrations, although increased, remained constant (table 1).

Discussion

We have confirmed a well-defined change in cardiovascular status after graft reperfusion during orthotopic liver transplantation, consisting of marked reduction in systemic vascular resistance and an increase in cardiac output. We have also demonstrated significant changes in circulating concentrations of mediators of inflammation, including cytokines and eicosanoids, after reperfusion.

The endothelium produces several substances which regulate inflammation, including cytokines and arachidonic acid metabolites. Orchestration of the inflammatory response depends on communication between cells by cytokines which regulate the severity and duration of the inflammatory response.

In this study we found increases in TNFα, IL-1β, IL-6 and IL-8 1 h after reperfusion. This contrasts with models of endotoxin-induced sepsis, where increases in TNF concentration in the circulation usually preceded increases in IL-6 and IL-8 by several hours.[13] A previous study also found early intraoperative increases in IL-6.[14] A possible explanation in our patients could be cytokine activation as a result of veno-venous bypass. Cardiopulmonary bypass can trigger an early increase in IL-6 and neutrophil activity.[15 16] Another possibility could be "priming" by high circulating concentrations of PAF seen in this study.

Cytokines produce a biological effect which is receptor mediated. Specific cytokine receptor expression is itself cytokine dependent. Additionally, the interaction between cytokine and receptor may be modulated by the effects of free (circulating) receptor molecules or by circulating antagonists to cellular receptors. The biological action of IL-1β for example is regulated by its receptor antagonist (IL-1ra) and regulated independently by other cytokines as part of the inflammatory process. In addition to increased cytokine concentrations, predictable concomitant increases in IL-1ra and TNF receptor 1 (TNF-R1, a circulating TNF receptor possibly antagonizing the interaction between TNF and its cellular receptor) were found in our study after reperfusion.

Under conditions of ischaemia and reperfusion, oxygen-derived free radicals are produced by activation of xanthine oxidase. We have shown previously increased oxidant stress after graft reperfusion during liver transplantation, associated with haemodynamic changes.[4 17] In this study we have demonstrated elevation of thromboxane B_2 and total leukotrienes in varying proportions in different patients. Oxygen-derived free radicals mediate production of both thromboxanes and leukotrienes.[6] These vasoactive compounds with oxygen derived free radicals act as chemoattractants for leucocytes. Moreover, eicosanoids have been implicated in the increases in intracellular calcium in the leucocyte which trigger cytokine expression.

Lipid mediators of inflammation include PAF and arachidonic acid metabolites. PAF primes macrophages to other inflammatory mediators and alters microvascular permeability. Although PAF did not increase as a result of reperfusion, concentrations were increased compared with previous findings in healthy subjects.[18] Arachidonic acid metabolites, including leukotrienes and thromboxanes, have profound inflammatory and vascular actions and may regulate, and be regulated by, cytokines.

We have shown that in patients undergoing liver transplantation there was an inflammatory response associated with expression of several pro-inflammatory cytokines subsequent to reperfusion in humans. This was accompanied by activation of lipoxygenase and cyclo-oxygenase pathways suggesting ongoing inflammatory activation and endothelial damage. These changes occurred in association with dramatic characteristic haemodynamic changes of the reperfusion syndrome. These changes in cytokines, biochemistry and haemodynamic state resemble those seen in the sepsis syndrome, although unlike septic shock they are precisely predictable. Other workers have shown an association between increases in intraoperative TNFα and IL-6 concentrations with subsequent graft rejection and infection.[14] An understanding of the biochemical and inflammatory processes surrounding graft reperfusion may therefore lead to strategies to improve outcome. We have not considered in this study the role of anti-inflammatory cytokines and further work is required.

Environmental monitoring during gaseous induction with sevoflurane

J. E. HALL, K. A. HENDERSON, T. A. OLDHAM, S. PUGH AND M. HARMER

Summary

Recent research has shown that gaseous induction in adults with sevoflurane is an acceptable technique. This study was undertaken to assess if gaseous induction using sevoflurane carried in both oxygen alone, and in nitrous oxide and oxygen combined, would provide acceptable pollution levels. As an occupational exposure standard has not been set for sevoflurane, we used the target level of 20 ppm set by the manufacturer. Environmental monitoring was carried out in the anaesthetic room during eight lists where consecutive triple vital capacity sevoflurane inductions were performed. Time-weighted averages for both gases over the duration of the lists were well below the occupational exposure standards (mean 1.1 (range 0.6–1.7) for sevoflurane and 17.3 (12–23) for nitrous oxide). There were high peak concentrations during the induction process (8.3 (4.1–17) for sevoflurane and 172.4 (65–310) for nitrous oxide) although these decreased to low concentrations between anaesthetic inductions. Personal sampling was carried out from the anaesthetist's breathing zone and concentrations were also low (1.2 (0.8–2.1) for sevoflurane and 45.9 (10.1–261.6) for nitrous oxide. (*Br. J. Anaesth.* 1997; **79**: 342–345).

Key words
Anaethetics volatile, sevoflurane. Operating rooms, contamination.

Gaseous induction of anaesthesia is possible with sevoflurane in adults because of its low blood-gas solubility and non-irritant nature.[1] Several studies have demonstrated rapid induction of anaesthesia with high concentrations of the gas. Both tidal volume[2] and vital capacity[3] inductions have been tried successfully at high concentration with perhaps the latter technique being slightly faster and smoother. Gaseous induction with sevoflurane appears to be safe in patients for induction, but the effect on pollution levels in the anaesthetic room is not known.

This study was undertaken to determine pollution levels in the anaesthetic room concomitant with high concentration, triple vital capacity induction in adults using sevoflurane. An occupational exposure level of 20 ppm has been set by the manufacturers of sevoflurane. During three lists, nitrous oxide was monitored to assess the acceptability of using this agent in the fresh gas flow during induction.

Materials and methods

Environmental pollution was studied during eight consecutive orthopaedic lists where a relatively high turnover of patients was expected. Sevoflurane was monitored during five lists when there were 23 inductions, while nitrous oxide was monitored during three lists when there were 12 inductions. There were six personal samples obtained measuring sevoflurane concentrations and nine measuring nitrous oxide concentrations. Monitoring was performed in the anaesthetic room and all breathing systems were subject to active scavenging by a Venturi injector system operated by an 8 litre min^{-1} oxygen source on the anaesthetic machine. Consecutive gaseous inductions were performed with no i.v. inductions. Sevoflurane and nitrous oxide were used for maintenance of anaesthesia in theatre so that inadvertent spillage of anaesthetic gases could be monitored as this might affect background pollution levels.

Two methods of environmental monitoring were used, background sampling and personal sampling.

BACKGROUND ENVIRONMENTAL SAMPLING

Environmental pollution associated with the use of a Bain breathing system (co-axial Mapleson D) was examined. All inductions were performed in one of two anaesthetic rooms and air changes were measured formally in these rooms using sulphur hexafluoride and an infrared spectrometer. Twenty-five inductions were carried out in one anaesthetic room and 10 in the other.

Environmental monitoring of the anaesthetic gases was performed using a MIRAN 1B. This is a portable ambient air analyser which uses a single beam infrared spectrophotometer to measure background air pollution in working environments. Nitrous oxide was sampled at a wavelength of 4.68 μm and sevoflurane at 8.9 μm. The MIRAN was calibrated using the MIRAN closed-loop calibration

system before starting the study by introducing a known volume of anaesthetic agent into the MIRAN.

The MIRAN probe was positioned between 80 and 120 cm from the patient's head, behind and slightly to one side of the anaesthetist in an attempt to sample the highest concentrations of volatile agent. Monitoring was carried out for the whole theatre list to obtain a picture of the peaks and troughs throughout the day. Data were transferred onto a data logger and this information was then converted to graphical form.

The following gaseous induction techniques were used.

Sevoflurane monitoring

After preoxygenation, the patient was instructed to take a deep inspiration of 100% oxygen, and during the subsequent expiration, the inspired gas composition was changed to the induction mixture of 8% (dial) in oxygen. Induction then commenced with the patient taking three consecutive vital capacity breaths, the third breath being held for as long as possible. When patients were unable to hold this breath any longer, they were allowed to breathe normally. Patients were instructed in the induction technique before operation. Initially fresh gas flows of 9 litre min^{-1} were used, which were reduced to 6 litre min^{-1} after loss of consciousness. The high gas flow technique ensured a rapid increase in the inspired concentration of sevoflurane necessary for rapid induction. The time taken for the inspired concentration of sevoflurane to increase to greater than 7% was approximately 5–6 s. Inspired gas concentrations were measured using a Capnomac Ultima monitor (Datex, Helsinki, Finland) via a sampling cannula placed between the distal end of the breathing system and the face mask. Jaw relaxation was tested every 30 s after loss of consciousness and a laryngeal mask airway was inserted when this was achieved. During insertion of the laryngeal mask airway, the breathing system was placed on the pillow next to the patient's head with the fresh gas flow still running; 23 inductions were carried out using this technique.

Nitrous oxide monitoring

In inductions where nitrous oxide was monitored, the induction technique was as described above, except that the induction mixture, when commenced, was 8% sevoflurane carried in nitrous oxide and oxygen (ratio 2:1); 12 inductions were carried out using this technique.

Gaseous inductions were carried out by two of the authors (J. E. H. and S. P.). Both anaesthetists were familiar with the triple vital capacity breath induction technique.

PERSONAL SAMPLING

This was carried out using a 1-litre gas reservoir connected to a personal sampling pump. It was attached to the anaesthetist and sampled air directly from the breathing zone. Sampling was carried out over 1 h during which time one or two gaseous inductions were performed to give a single result. The gas sample was then analysed using the MIRAN 1B. Exposure of the anaesthetist during the hour of sampling was calculated taking into account the volume of the personal sampling system.

Results

Air changes in both anaesthetic rooms were within acceptable limits,[4] one room having 15 changes per hour (where 10 inductions were carried out) and the other 17 air changes per hour (where 25 inductions were carried out).

BACKGROUND EXPOSURE

Background exposures were low when assessed as time-weighted averages (TWA) (table 1). Conventionally it is usual to express TWA over an 8-h period but the operating lists were not so prolonged, and values were averaged over the period of each list. Peaks of both sevoflurane and nitrous oxide during induction of anaesthesia were followed rapidly by low background concentrations. All peaks for sevoflurane were less than 20 ppm and most were less than 10 ppm. Occasional higher results could be explained by an incident during anaesthesia (for example during induction with a sevoflurane peak of 17 ppm, the size 4 laryngeal mask airway was removed and replaced by a size 5 airway causing some extra pollution). There was more variability in the peak values for nitrous oxide, although TWA values were also below the occupational exposure standard (OES).

PERSONAL EXPOSURE

Personal sampling during induction and maintenance of anaesthesia revealed low exposure. One nitrous oxide personal sample appeared to be unusually high (261 ppm). This bag was removed at one point from the anaesthetist while still sampling and placed on the anaesthetic machine. It is possible that it came into contact with concentrated nitrous oxide during a circuit break at this time.

Table 1 Peak, personal reservoir sample and time weighted average gaseous concentrations (mean (range))

	Peak levels (ppm)	Time weighted average (ppm)	Personal reservoir sample concentration (ppm)
Sevoflurane	8.3	1.1	1.2
(5 lists, 23 inductions, 6 personal samples)	(4.1–17.0)	(0.6–1.7)	(0.8–2.1)
Nitrous oxide	172.4	17.3	45.9
(3 lists, 12 inductions, 9 personal samples)	(65–310)	(12–23)	(10.1–261.6)

Discussion

While there is at present no official OES for sevoflurane, it is a halogenated ether, similar to enflurane and isoflurane, both of which have an OES of 50 ppm.[5] Target compliance with this level is probably sensible. Abbott Laboratories, the manufacturers of sevoflurane, have suggested a limit of 20 ppm.[6] This was set to be 100 times lower than the level which would have any clinical effect (i.e. 2000 ppm). These two limits have been chosen arbitrarily, but the 20 ppm limit is conservative compared with levels for isoflurane and enflurane, although the OES for halothane is 10 ppm. With the 20 ppm limit in mind it seems that high concentration sevoflurane induction in adults complies with the environmental standard. Monitoring was also carried out during gaseous induction with sevoflurane carried in combined nitrous oxide and oxygen. The OES for nitrous oxide is 100 ppm, and the TWA complied with this

Using the personal sampling apparatus, samples were obtained directly from the breathing zone of the anaesthetist to provide a clearer picture of personal exposure. More marked increases in volatile concentration could have been expected, but this was not manifest and the anaesthetists received low exposures. There was one high result among the nitrous oxide samples which may have been caused by intraoperative breathing system disconnection.

The Mapleson A breathing system was used in an early gaseous induction study[7] and has been used subsequently[8] but it is probably not the best system for the vital capacity technique because of the need to prefill the breathing system. This necessitates changing from a separate preoxygenation system, probably causing environmental spillage. In addition, the technique is quite cumbersome, extra equipment is needed in theatre and the stopper on the system may dislodge causing further pollution. The use of high fresh gas flows with the Bain allows induction to be carried out with a single breathing system. The Bain can be used conveniently for gaseous induction without necessitating changing the system after preoxygenation. It was decided not to examine pollution associated with the circle system because this is used infrequently in the anaesthetic room in our own practice. Gaseous induction with a circle system would probably be economical to use and associated with low pollution, if anaesthesia was induced in theatre. The circle system has been used for halothane gaseous induction[9] and environmental monitoring would be of interest to hospitals using this breathing system for induction and in countries which do not use anaesthetic rooms.

The marked influence of individual anaesthetists on levels of environmental pollution has been demonstrated by Gray and Spence[10] who found that the anaesthetist's exposure varied by a factor of 17 on a day-to-day basis. The influence of different techniques cannot be underestimated and our highest sevoflurane peak was associated with change of a laryngeal mask airway. The anaesthetics in this study were conducted by two different anaesthetists who, although both familiar with the triple vital capacity gaseous induction technique, would inevitably use slightly different anaesthetic techniques. This variation aside, using the prescribed method, neither anaesthetist produced pollution of such levels that the OES values were contravened.

Anaesthetists are exposed constantly to low levels of volatile anaesthetic agents. Early epidemiological research which examined occupational health exposure was often poorly controlled. A large body of research has examined the biological effect of chronic exposure on animals. Work in rats has shown nitrous oxide to be associated with a lower implantation rate and a higher fetal death rate.[11] In addition, production of smaller rat litters and increased skeletal malformation have also been demonstrated.[12] Volatile agents have also been implicated in animal work with skeletal anomalies being demonstrated after 12-h exposure to 0.8% halothane in rats.[13] Extrapolation to humans is of course difficult, but by the late 1980s there was a sufficient body of evidence to negate the association between human developmental toxicity and nitrous oxide.[14] A 10-yr prospective study was undertaken by Spence,[15] the results of which have been partially reported to the Medical Research Council. Initial results would seem to suggest that anaesthesia is not associated with an occupational health risk.

The OES were set by the Health and Safety Executive to be well below the levels thought safe for animals. There may be little convincing evidence to show an association between low anaesthetic exposure and toxicity, but high levels do have an effect and it is sensible to maintain a low level of occupational exposure to any potentially toxic substance. The 1994 regulations of the control of substances hazardous to health and the occupational exposure standards for the four named anaesthetic agents have been enforced since January 1996 in an attempt to control the anaesthetist's working environment. It appears that gaseous induction with sevoflurane with or without nitrous oxide administered by the technique we have described complies with environmental standards and lack of compliance is not a bar to the potential of sevoflurane as a single agent anaesthetic.

LABORATORY INVESTIGATIONS

Effect of haemoglobin concentration on brain oxygenation in focal stroke: a mathematical modelling study

F. DEXTER AND B. J. HINDMAN

Summary

Acute perioperative anaemia may affect neurological injury from permanent focal ischaemic insults. We modelled the opposing effects of haemodilution (increasing cerebral blood flow, decreasing arterial oxygen content) on oxygen availability and uptake in the ischaemic penumbra. First, we validated a mathematical model of regional cerebral oxygen uptake by using published arterial oxygen content and cerebral blood flow values from normal rabbits with progressive anaemia. Then we applied the model to the problem of interest (i.e. the ischaemic penumbra of a focal embolic stroke). We re-analysed published experimental data giving the cerebral blood flow response to anaemia in the ischaemic penumbra. Penumbral extraction reserves were nearly exhausted at a haemoglobin concentration of approximately 10 g 100 ml^{-1}. Oxygen uptake in the ischaemic penumbra decreased progressively when haemoglobin concentrations decreased to less than 10 g 100 ml^{-1}. We conclude that, given the available clinical and experimental literature, and until a suitable randomized clinical study has been performed, a haemoglobin concentration of 10 g 100 ml^{-1} is the rational transfusion "trigger" for the acutely anaemic stroke patient. (*Br. J. Anaesth.* 1997; **79**: 346–351).

Key words
Blood, haemoglobin. Brain, metabolism. Brain, blood flow. Brain, ischaemia. Blood, haemodilution. Complications, anaemia. Model, mathematical.

More than half a million adults undergo cardiac surgery in Europe and North America each year.[1] Modern cardiac surgery includes operative blood loss, deliberate haemodilution and the desire to limit homologous transfusion. Thus cardiac surgery patients often have haemoglobin concentrations of 7–9 g 100 ml^{-1} for several days after operation. Currently, 3–5% of cardiac surgery patients also sustain a perioperative cerebral infarction (stroke).[2 3] It is not known if the marked postoperative anaemia of cardiac surgery patients affects their neurological outcome. Laboratory[4–7] and clinical studies[8–11] have provided conflicting results. In some studies haemodilution improved neurological outcome[4 5 8 9]; by increasing cerebral blood flow (CBF), haemodilution may have improved oxygenation of marginally viable brain (the "ischaemic penumbra"). Other studies have found an adverse effect with haemodilution.[6 7 10 11] Under these circumstances, reduced arterial oxygen content may have more than offset increased CBF and resulted in a net reduction in oxygen delivery to the penumbra. In this study, we have modelled the opposing effects of haemodilution (increasing CBF, decreasing arterial oxygen content) on oxygen availability and uptake in the ischaemic penumbra.

Our goal in this study was to see if there was a haemoglobin concentration below which penumbral oxygenation would be impaired rather than improved. Until a suitable randomized clinical study has been performed, such a predicted haemoglobin concentration would be a rational "transfusion trigger" for the anaemic, normothermic stroke patient.

Materials and methods

We adapted our previously described mathematical model of cerebral oxygen transport.[12] We used this model to predict regional cerebral oxygenation in normal and penumbral brain as a function of arterial haemoglobin concentration. There are no human CBF data covering a wide range of haemoglobin concentrations in acute stroke. Thus we used CBF and cerebral metabolic rate for oxygen (CMR_{O_2}) data obtained from rabbits. CBF responses to haemodilution are known for this species, both in the presence[13] and absence[13 14] of acute cerebral infarction.

We assumed a constant blood and brain temperature of 37 °C. At 37 °C, the human oxyhaemoglobin dissociation curve is described by the following relationship[15]:

$$S_{O_2}=\{[23400\,(P_{O_2}^{3}+150\,P_{O_2})^{-1}]+1\}^{-1} \qquad (1)$$

where S_{O_2} (unitless) = fractional oxyhaemoglobin saturation and P_{O_2} (mm Hg) = oxygen partial pressure. Diffusion primarily limits oxygen transfer from

haemoglobin to brain.[16] Hence we did not include chemical reaction kinetics in the model. The haemoglobin P_{50} of the rabbit (4.0 kPa) and Hill coefficient (2.8) are almost identical to those of humans (3.5 kPa and 2.9, respectively).[17 18] Therefore, human and rabbit oxyhaemoglobin saturation curves can be considered to be equivalent.

Net regional oxygen transport from blood to brain tissue (i.e regional brain oxygen uptake) is described using Fick's law of diffusion for a parallel plane layer geometrical configuration[19 20]:

$$\mathrm{rCMRO_2}= \left(\frac{11358}{27\times10^{-4}}\right)(2.9\times10^{-5}\times13\times(8.22\times10^{-4})\times Pec_{O_2}-Pin_{O_2} \qquad (2)$$

where $\mathrm{rCMR_{O_2}}$=regional $\mathrm{CMR_{O_2}}$ (ml O_2 100 g^{-1} min^{-1}), Pec_{O_2} (mm Hg)=regional end-capillary oxygen partial pressure and Pin_{O_2} (mm Hg)=regional interstitial oxygen partial pressure. The term 11 358 cm^2 100 g^{-1}=the sum of arteriole, capillary and venule surface areas available for oxygen exchange[21]; the term 27×10^{-4} cm=the sum of capillary and tissue thickness[20]; the term 2.9×10^{-5} ml O_2 ml^{-1} mm Hg^{-1}=oxygen solubility in brain at 37 °C[22]; the term 8.22×10^{-4} cm^2 min^{-1} specifies the net oxygen diffusion coefficient in blood and brain[23]; 13 (unitless) is a correction factor shown by Schacterle, Ribando and Adams to be necessary for Fick's law to attain the level of oxygen transport measured experimentally.[24] The correction is needed because oxygen diffuses intracellularly through areas of high solubility (i.e. lipid).[25] Thus this correction factor has been shown to come from the oxygen diffusion properties of lipids. As such, it is unlikely to be affected by changes in regional CBF, intracellular pH, etc, as may occur in the ischaemic penumbra. Also, the factor is unlikely to vary greatly among species.

$\mathrm{rCMR_{O_2}}$ can be determined by mass balance[19]:

$$\mathrm{rCMR_{O_2}}=\mathrm{rCBF}\ (1.34\ \mathrm{Hb}\ Sa_{O_2}+\alpha_{bl}\ Pa_{O_2}-1.34\ \mathrm{Hb}\ Sec_{O_2}-\alpha_{bl}\ Pec_{O_2}) \qquad (3)$$

where rCBF=regional CBF (ml $g^{-1}min^{-1}$), Hb=haemoglobin concentration (g 100 ml^{-1}); α_{bl}=oxygen solubility in blood (0.0029 ml O_2 100 ml^{-1} mm Hg^{-1}),[19] Sa_{O_2} (unitless)=arterial oxyhaemoglobin saturation, Pa_{O_2} (mm Hg)=arterial oxygen partial pressure and Sec_{O_2} (unitless)= cerebral end-capillary oxyhaemoglobin saturation. Our model is for cardiac surgery patients undergoing mechanical ventilation and therefore we used $Pa_{O_2}=100$ mm Hg and $Sa_{O_2}=1.0$ in all simulations.

Todd, Weeks and Warner recently reported that, in rats, brain haemoglobin concentration is less than systemic arterial haemoglobin concentration.[26] Other groups have not confirmed this finding.[27] Nevertheless, whole brain haemoglobin concentration can be less than systemic arterial and jugular haemoglobin concentrations, if erythrocytes travel through the capillary beds faster than plasma.[26] Thus the experimental findings of Todd, Weeks and Warner do not change the validity of mass balance for the amount of oxygen being delivered to and leaving the brain.[26] Equation (3) only uses haemoglobin concentration in this manner (i.e. to specify mass balance for oxygen for a region of brain).

Regional cerebral oxygen consumption varies with interstitial oxygen partial pressure[24 28]:

$$\mathrm{rCMRO_2}=\frac{3.5\times Pin_{O_2}}{Pin_{O_2}+2.0} \qquad (4)$$

Normal human $\mathrm{rCMR_{O_2}}$=3.5 ml O_2 100 g^{-1} min^{-1}.[29] The term 2.0 mm Hg specifies the interstitial oxygen partial pressure at which $\mathrm{rCMR_{O_2}}$ is 50% of normal.[29] Thus, as interstitial oxygen partial pressure increases, $\mathrm{rCMR_{O_2}}$ asymptotically approaches a maximal (normal) value. Back, Kohno and Hossmann found that brain interstitial oxygen partial pressures were 28 mm Hg in normothermic rats.[30] Substituting this value into equation (4) gives a $\mathrm{rCMR_{O_2}}$ value of 93% of normal. We consider 93% to be a value clinically indistinguishable from normal. Conveniently, 3.5 ml O_2 100 g^{-1} min^{-1} is not only a normal $\mathrm{rCMR_{O_2}}$ value for awake humans, but also in anaesthetized rabbits.[31] This equivalence allows the use of rCBF and $\mathrm{rCMR_{O_2}}$ data from anaesthetized rabbits with acute embolic stroke to estimate the effect of anaemia on the human ischaemic penumbra.

We first tested the validity of the model; to do this we checked that the model predicted the effect of haemodilution on cerebral oxygenation ($\mathrm{CMR_{O_2}}$, oxygen extraction) in normal brain. We used data from Todd and colleagues.[14] They decreased the haemoglobin concentration of anaesthetized rabbits from 13 to 4.5 g 100 ml^{-1} and measured changes in CBF, oxygen extraction and $\mathrm{CMR_{O_2}}$. We inserted their values for mean haemoglobin concentration, arterial oxygen contents and CBF into our model. Algebraic equations (1)–(4) were numerically solved simultaneously.[32] Solutions for $\mathrm{CMR_{O_2}}$ were constrained to be less than or equal to the maximal (normal) $\mathrm{CMR_{O_2}}$.[32] Iterations were continued until $\mathrm{CMR_{O_2}}$ was calculated to within 0.01%. We compared predicted $\mathrm{CMR_{O_2}}$ and oxygen extraction ratios with those measured by Todd and colleagues.[14]

Next we modelled the effect of anaemia on penumbral oxygenation; to do this we used the CBF data of Korosue and Heros.[13] They measured rCBF in the ischaemic penumbra of rabbits after embolic stroke and acute isovolaemic haemodilution, and simultaneously measured rCBF in the non-embolized contralateral hemisphere:

$$\mathrm{rCBF}=\begin{cases}0.384\ (-7\ 4\ (1.34\ \mathrm{Hb}\ Sa_{O_2}+\alpha_{bl}Pa_{O_2})+212.7), & \text{normal brain} \\ 0.201\ (-3.0\ (1.34\ \mathrm{Hb}\ Sa_{O_2}+\alpha_{bl}Pa_{O_2})+150.4), & \text{ischaemic penumbra}\end{cases} \qquad (5)$$

As before, algebraic equations (1)–(4) were solved simultaneously to determine $\mathrm{rCMR_{O_2}}$ and oxygen extraction as a function of haemoglobin concentration.

Results

We first used data from Todd and colleagues[14] to test the model. Table 1 gives measured and

Table 1 Comparison of model predictions with data from Todd and colleagues.[14] Model parameters are the mean experimental values which were substituted into the mathematical model. The maximum normal cerebral metabolic rate for oxygen ($CMRo_2$) was set equal to the maximum observed mean $CMRo_2$ (4.0 ml O_2 100 g^{-1} min^{-1}), rather than 3.5 ml O_2 100 g^{-1} min^{-1}, as used in equation (4). Measured oxygen extraction ratio and $CMRo_2$ are reported as mean (SD) (n=6). CBF=Cerebral blood flow

Model parameters			Measured		Predicted

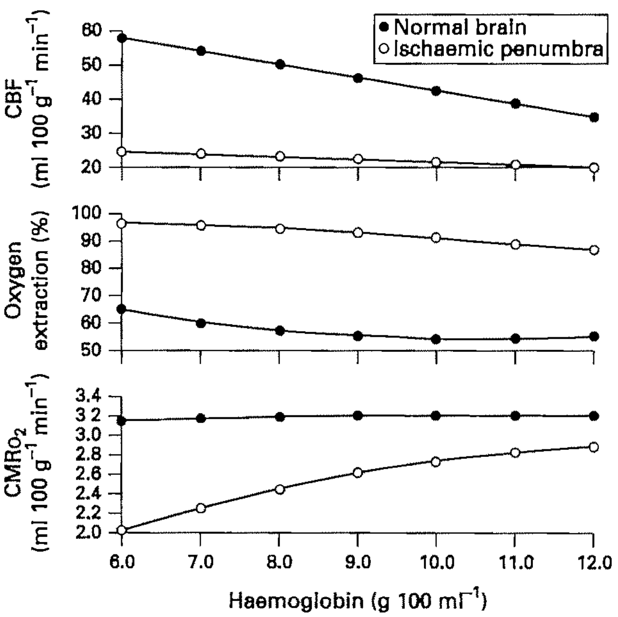

Figure 1 Dependence of oxygen extraction and cerebral metabolic rate ($CMRo_2$) on cerebral blood flow (CBF) and haemoglobin concentration. The mathematical model predicts regional oxygen extraction and cerebral metabolic rate for oxygen (CMR_{O_2}) given regional CBF and haemoglobin concentration. Experimental data[13] give regional CBF as a function of haemoglobin concentration, in normal brain and in the ischaemic penumbra of a middle cerebral artery infarction (top). CBF and haemoglobin concentration are then used as inputs in the mathematical model to predict regional oxygen extraction (middle) and regional CMR_{O_2} (bottom).

predicted values of CMR_{O_2} and oxygen extraction during acute isovolaemic haemodilution in rabbits. Our model predictions were well within the error of their measurements. Hence, our model accurately predicted brain oxygen extraction and the resulting CMR_{O_2} in the presence of acute isovolaemic haemodilution. These data also show that, in normal brain, the increase in CBF with haemodilution does not fully compensate for decreased arterial oxygen content. Thus to maintain normal CMR_{O_2}, the brain increases oxygen extraction. The increase in extraction is sufficient to preserve CMR_{O_2}, even in the presence of very severe anaemia (haemoglobin concentration as low as 4 g100 ml^{-1}).

Having validated our model, we next applied it to the problem of interest. In figure 1 (top), we show measured[13] rCBF as a function of arterial haemoglobin concentration. Haemodilution increased CBF in both normal brain and ischaemic penumbra. However, the magnitude of the increase was much less in the ischaemic penumbra than that in normal brain (fig. 1, top). In the non-ischaemic brain, reduction in haemoglobin concentration from 12 to 6 g100 ml^{-1} caused a 65% increase in CBF (or 23 ml 100 g^{-1} min^{-1}). However, in the ischaemic penumbra, the same reduction in haemoglobin concentration caused CBF to increase by only 24% or 5 ml 100 g^{-1} min^{-1}.

The measured CBF *vs* haemoglobin relationships from figure 1 were used as inputs in our mathematical model. Regional brain oxygen uptake (i.e. CMR_{O_2}) was predicted from the haemoglobin concentration (fig. 1). The model predicted that, at a haemoglobin concentration of 12 g 100 ml^{-1}, $rCMR_{O_2}$ in the ischaemic penumbra is only slightly (10%) less than that in normal tissue (2.9 *vs* 3.2 ml 100 g^{-1} min^{-1}) (fig. 1, bottom), because of greater oxygen extraction (fig. 1, middle). This model prediction is consistent with experimental studies of regional oxygen metabolism in focal cerebral ischaemia. Acutely, penumbral CMR_{O_2} has been found to be only 7–20% less than that of non-ischaemic brain.[33–35]

For the non-ischaemic brain, the model predicted that increases in CBF from anaemia do not fully compensate for decrease in arterial oxygen content. A moderate increase in oxygen extraction is needed to maintain normal brain oxygen uptake (fig. 1, middle). However, with this increase, normal brain maintains oxygen uptake, even with marked anaemia. As stated before, this model prediction is consistent with the study of Todd and colleagues[14] of isovolaemic anaemia in rabbits (table 1).

In contrast, the model predicted that, in the ischaemic penumbra, increased CBF (fig. 1, top) and oxygen extraction (fig. 1, middle) are *not* sufficient (fig. 1, bottom) to compensate for decreases in arterial oxygen content. Oxygen uptake ($rCMR_{O_2}$) in the ischaemic penumbra decreased progressively with greater anaemia. For example, at a haemoglobin concentration of 6 g 100 ml^{-1}, predicted oxygen uptake in the ischaemic penumbra was 36% less than that in non-ischaemic brain. Our model predicted that anaemia of less than 10 g 100 ml^{-1} decreased oxygen availability to penumbral tissue.

Discussion

PREVIOUS CLINICAL AND LABORATORY STUDIES

Cardiac surgery patients sustain perioperative cerebral infarction at a rate exceeding 3%.[23] They are also routinely haemodiluted to haemoglobin concentrations of 7–9 g 100 ml^{-1}. It is not clear if, after operation, red blood cell transfusion may improve neurological outcome. There is evidence to suggest that it may. Neuropsychological impairment 9 days after cardiac surgery is associated with haemoglobin concentrations of less than 10 g 100 ml^{-1} in the first 12 h after surgery.[36] Also, acute neurological and neuropsychological outcome is significantly worse in cardiac surgery patients with the greatest perioperative reductions in haemoglobin concentration.[37] Lee and colleagues used a middle cerebral artery occlusion model in dogs.[7] They found that infarction volumes were less in animals with a haemoglobin concentration of 10 g 100 ml^{-1} than in those with a concentration of 8 g 100 ml^{-1}. Similarly, we recently used an embolic stroke model in rabbits.[6] Animals allocated randomly to a haemoglobin concentration of 6 g 100 ml^{-1} had larger infarction volumes than those allocated to a haemoglobin concentration of 11 g 100 ml^{-1}. Collectively, these studies suggest that acute anaemia can exert a detrimental effect on neurological outcome, especially when postoperative haemoglobin concentrations are less than 10 g 100 ml^{-1}. Our model predictions strongly support this suggestion.

PENUMBRAL OXYGEN UPTAKE

Our model predicted that at haemoglobin concentrations of 10–12 g 100 ml^{-1}, increased CBF and oxygen extraction were sufficient to permit penumbral oxygen uptake to remain nearly normal. As stated previously, this result is consistent with the experimental literature. However, the model predicted that there is an abrupt decrease in penumbral oxygen uptake when haemoglobin concentrations decrease to less than 10 g 100 ml^{-1}. This is because, in the ischaemic penumbra, increases in CBF and oxygen extraction are insufficient to compensate for decreases in arterial oxygen content when haemoglobin concentrations are less than 10 g 100 ml^{-1}. Penumbral oxygen extraction reserves are nearly exhausted even after only moderate anaemia (haemoglobin concentration of 12 g 100 ml^{-1}). Progressively greater degrees of anaemia limit oxygen uptake in the ischaemic tissue.

Optimal management of patients with acute perioperative stroke should include efforts to support penumbral oxygenation. Penumbral tissue sustains a series of membrane depolarizations in the hours after onset of focal ischaemia.[30 38–41] These depolarizations, lasting 5–10 min,[30] do not change penumbral CBF, but appear to transiently increase cerebral metabolism. The increase in cerebral metabolism is probably a result of the increased ion pump activity needed to re-establish transmembrane ionic homeostasis.[40 42] Therefore, ischaemic membrane depolarizations increase penumbral energy requirements, exacerbating the mismatch between metabolic demand and substrate supply.[30] This mismatch may explain why the number and duration of depolarizations correlate(s) with final infarction volume.[38 39 41] Haemoglobin concentrations less than 10 g 100 ml^{-1} progressively limit oxygen availability to the penumbra. Thus marked anaemia seems likely to slow restoration of ionic homeostasis. Doing so may promote a more rapid deterioration of the penumbra. Rapid deterioration of the penumbra converts what was potentially salvageable tissue into infarct.[41]

ROLE OF MATHEMATICAL MODELLING

Factors other than haemoglobin concentration have important effects on neurological outcome, such as the timing of therapy, species studied, vascular territories involved and arterial pressure. These factors, almost certainly, are responsible for some of the discrepancies between previous studies.[4–11] The regional CBF data of Korosue and Heros[13] were obtained at normal arterial pressures and temperatures. Thus our model predictions apply to the condition of normotension and normothermia. On the other hand, the mechanism of CBF response to haemodilution (e.g. viscosity *vs* metabolism) is of no importance to our model predictions. CBF is an independent variable in the mathematical model (eqn (5)). The magnitude of the CBF response to haemodilution is important and may depend on both the viscosity characteristics of the haemodilutant and arterial oxygen content.[43] Korosue and Heros used plasma to haemodilute their rabbits,[13] while Todd and colleagues used hetastarch.[14] Our results apply to acute haemodilution with similar substances. Haemodilution with cross-linked haemoglobin would, for example, be expected to give results different from those predicted by our model.[43]

The multiple factors that can influence neurological outcome demonstrate the advantage of using mathematical modelling. We focused only on haemoglobin concentration (fig. 1). The mathematical model used in this study was intentionally simplistic with respect to the process of oxygen diffusion from blood to brain. Decisions to apply existing models to this study were based on four limitations. First, terms must have been measured under the conditions of focal embolic stroke. The only values that have been measured reliably are regional CBF (i.e. Korosue and Heros' rabbit data[13]). Additional dependent variables, such as intracapillary red blood cell spacing and spatial heterogeneity of red blood cell flow, are not available. Additional experimental data are not likely to be forthcoming soon. Tissue P_{O_2} electrodes could be placed into the ischaemic penumbra. However, as equation (4) shows, tissue P_{O_2} and regional CMR_{O_2} are not equivalent. The model makes predictions for the effect of haemodilution on regional CMR_{O_2}, not tissue P_{O_2}. Furthermore, to identify the ischaemic penumbra, simultaneous regional CBF measurements would be needed. The only technique that can accomplish both of these requirements is positron emission tomographic scanning. Second, CBF data were available only for gross regions of the brain,[13] not at the microcirculatory level. Thus a model based on space-averaged oxygen tensions was necessary. Third, we used CBF and CMR_{O_2} data obtained from rabbits. Korosue and Heros[13] also studied rabbits. Rabbits and humans share many key physiological characteristics (cerebrovascular anatomy, arterial pressure, haemoglobin concentration, CBF, CMR$_{O_2}$, haemoglobin P$_{50}$ and co-operativity). Hence, conclusions regarding cerebrovascular physiology derived from rabbit data are likely to be applicable to humans. Fourth, not all of the biophysical variables we needed were available for rabbits or humans. Biophysical transport variables from species other than rabbits would not be expected to differ significantly. Therefore, we doubt that this limitation had much effect on the simulation results, at least qualitatively. Additional model complexity would not have compensated for this latter weakness. Thus increased model complexity would not have substantively increased model accuracy. However, despite our model's limitations, *it successfully predicted* the data of Todd and colleagues[14] (table 1). The basic processes of regional brain oxygen uptake alone can *accurately predict* the effect of anaemia on oxygen extraction. We used the mathematical model to make clinically significant predictions only *after we had verified* the validity of the model.

CLINICAL SIGNIFICANCE

An American Society of Anesthesiologist's task force recently published practice guidelines for blood component therapy.[44] The task force concluded that red blood cell transfusion is rarely indicated when the haemoglobin concentration exceeds 10 g 100 ml^{-1} but is almost always appropriate when it is less than 6 g 100 ml^{-1}. In addition, the task force concluded that "the determination of whether intermediate haemoglobin concentrations (6–10 g 100 ml^{-1}) justify or require red blood cell transfusion should be based on the patient's risk for complications of inadequate oxygenation." Our results showed that, in the presence of an acute focal stroke, penumbral oxygenation is likely to be inadequate at haemoglobin concentrations less than 10 g 100 ml^{-1}. Our model predictions do not stand in isolation; they are consistent with other clinical[36 37] and laboratory[6 7] studies. All of these studies suggest that haemoglobin concentrations less than 10 g 100 ml^{-1} worsen neurological outcome after embolic stroke. We conclude that, given the available clinical and experimental literature, and until a suitable randomized clinical study has been performed, a haemoglobin concentration of 10 g 100 ml^{-1} is the rational transfusion "trigger" for the acutely anaemic stroke patient.

Actions of tramadol, its enantiomers and principal metabolite, O-desmethyltramadol, on serotonin (5-HT) efflux and uptake in the rat dorsal raphe nucleus

T. A. BAMIGBADE, C. DAVIDSON, R. M. LANGFORD AND J. A. STAMFORD

Summary

Tramadol is an atypical centrally acting analgesic agent with relatively weak opioid receptor affinity in comparison with its antinociceptive efficacy. Evidence suggests that block of monoamine uptake may contribute to its analgesic actions. Therefore, we have examined the actions of (±)-tramadol, (+)-tramadol, (−)-tramadol and O-desmethyltramadol (M1 metabolite) on electrically evoked 5-HT efflux and uptake in the dorsal raphe nucleus (DRN) brain slice, measured by fast cyclic voltammetry. Racemic tramadol and its (+)-enantiomer (both 5 μmol litre^{-1}) significantly blocked DRN 5-HT uptake (both $P<0.05$) and increased stimulated 5-HT efflux ($P<0.01$ (±)-tramadol; $P<0.05$ (+)-tramadol). The (−)-enantiomer and metabolite, O-desmethyltramadol, were inactive at the concentration tested (5 μmol litre^{-1}). For both (±)-tramadol and the (+)-enantiomer, the action on 5-HT efflux preceded an effect on 5-HT uptake, suggesting that uptake block was not the cause of the increased 5-HT efflux and that tramadol might therefore have a direct 5-HT releasing action. This activity, at clinically relevant concentrations, may help to explain the antinociceptive efficacy of tramadol despite weak μ opioid receptor affinity and adds to evidence that tramadol exerts actions on central monoaminergic systems that may contribute to its analgesic effect. (*Br. J. Anaesth.* 1997; **79**: 352–356).

Key words
Analgesics opioid, tramadol. Serotonin (5-hydroxytryptamine). Model, rat. Measurement techniques, voltammetry.

Tramadol is a centrally acting analgesic agent, effective in the treatment of moderate to moderately severe pain with a relatively low addiction potential.[1] A striking feature of the pharmacology of tramadol is its relatively weak opioid receptor affinity in comparison with its antinociceptive efficacy, indicative of the involvement of other mechanisms. Interestingly, its antinociceptive action in some animal models is only partially antagonized by naloxone,[2] strongly suggesting a non-opioid component to its analgesic potency. Furthermore, tramadol has an active metabolite, O-desmethyltramadol.[3]

Analgesia can be achieved both centrally and peripherally by interference with a variety of neurotransmitter systems. In particular, the control of pain is subject to descending modulation by brainstem cell groups such as the locus coeruleus/subcoeruleus and raphe complex.[4] These nuclei contain mainly noradrenaline and serotonin (5-HT), respectively.

Drugs that block noradrenaline uptake (such as desipramine) or that stimulate α_2 adrenoceptors (e.g. clonidine) are useful adjuncts to standard analgesic therapy in intractable pain and are also analgesic in their own right. Tramadol has been shown to block noradrenaline uptake in cortical synaptosomes and brain slices[5] thereby increasing noradrenaline efflux.[6] This and the fact that α_2 adrenoceptor blockade reduces its analgesic efficacy[7 8] indicates that enhancement of noradrenaline function contributes significantly to its analgesic profile.

The involvement of 5-HT in the descending control of pain is also widely recognized[4] and tramadol has been shown to enhance basal efflux of [^{3}H]-5-HT in frontocortical synaptosomes.[9] Tramadol also blocks 5-HT uptake[10] and it is thus possible that the effects of tramadol on cortical 5-HT efflux are mediated via uptake blockade. However, the synaptosome is such a highly reduced system, devoid of the transmitter interactions found *in vivo,* that it is not easy to draw conclusions on the relationship between 5-HT efflux and uptake inhibition.

Therefore, we chose to examine the actions of tramadol on 5-HT efflux and uptake in the dorsal raphe nucleus (DRN) brain slice, for four reasons. First, the dorsal raphe is part of the brainstem raphe complex and has been shown to have a role in the descending control of pain.[11] Second, the brain slice retains much of the local synaptic integrity and interactions of the whole animal while being easier to manipulate. Third, drug concentrations may be controlled precisely *in vitro,* thus allowing the elimination of pharmacokinetic considerations that

might confound data interpretation. Finally, the consequences of metabolism to active (or inactive) metabolites in the whole animal are excluded; this is particularly pertinent for tramadol.

Materials and methods

Fast cyclic voltammetry (FCV) at carbon fibre microelectrodes was used to determine the effects of tramadol, its enantiomers and principal metabolite on electrically stimulated 5-HT efflux and uptake in rat DRN brain slices. No Home Office-regulated procedures on live animals were performed.

PREPARATION OF SLICES OF THE RAT DORSAL RAPHE NUCLEUS

Male Wistar rats (150±25 g) were stunned and killed by rapid cervical dislocation. No prior anaesthesia was administered. The brain was excised rapidly and irrigated with ice-cold (−1 to +1 °C) artificial cerebrospinal fluid (aCSF). A Campden 752M vibratome was used to prepare 350-μm thick brainstem slices (+1.0 to +1.3 mm *vs* the interaural line[12]) containing the DRN (seen as a dove-shaped translucent area, ventral to the cerebral aqueduct). The brain slice was secured in a 1-ml volume superfusion-type brain slice tissue bath[13] by a nylon mesh drawn over a stainless steel grid. The internal temperature of the chamber was maintained at 32 °C and the slice was superfused with oxygenated (95% oxygen–5% carbon dioxide) aCSF at 1 ml min^{-1} throughout the experiment. Artificial CSF consisted of NaCl 124 mmol litre^{-1}, $NaHCO_3$ 25 mmol litre^{-1}, (+)-glucose 11 mmol litre^{-1}, KCl 2 mmol litre^{-1}, $CaCl_2$ 2 mmol litre^{-1}, $MgSO_4$ 2 mmol litre^{-1} and KH_2PO_4 1.25 mmol litre^{-1}.

MEASUREMENT OF 5-HT EFFLUX AND REUPTAKE BY FAST CYCLIC VOLTAMMETRY

A glass-coated carbon fibre (8 μm in diameter, 50 μm in length) recording electrode[14] was inserted 80 μm below the surface of the slice, approximately 200 μm from a bipolar tungsten stimulating electrode (A-M Systems, Seattle, USA). Figure 1A shows the basic set-up. The auxiliary (a 0.5-mm diameter stainless steel wire) and reference (Ag/AgCl cylinder) electrodes were positioned at a convenient location in the chamber.

Quantitative real time efflux of 5-HT was measured using FCV, as previously described.[15] An input voltage (1.5 cycles of a triangular waveform, −1.0 to +1.4 V *vs* Ag/AgCl, scan rate of 480 V s^{-1}) was applied to the potentiostat (Millar Voltammetric Analyser, PD Systems, West Molesey, UK) every 500 ms. The working electrode was disconnected between scans. The current output of the carbon fibre microelectrode was displayed on a digital storage oscilloscope (Nicolet 310DD). Background (charging) current signals before a stimulation were saved and subtracted from those obtained after a stimulus. Subtraction of one current signal from the other yielded the current caused by 5-HT oxidation and its subsequent reduction. A sample and hold circuit monitored the current at the oxidation potential for 5-HT (+570 mV *vs* Ag/AgCl). Its output was displayed on a chart recorder and stored on a microcomputer using CED (Cambridge Electronic Design) "Chart" software.

ELECTRICAL STIMULATION OF 5-HT RELEASE

All electrical stimulations were generated with standard Neurolog modules and applied to the stimulating electrode via an NL 800 constant current isolator. The slice was allowed to equilibrate in the chamber for at least 1 h before stimulation was conducted. 5-HT efflux was evoked by trains consisting of 20 pulses (0.1 ms duration, 10 mA constant current at 100 Hz) applied every 10 min.

On each stimulation, two variables were recorded: 5-HT efflux and uptake (see fig. 1B). 5-HT efflux was taken as the peak extracellular 5-HT concentration attained after stimulation. On cessation of stimulation, 5-HT was removed from the extracellular space by uptake. The "half-time" ($T_{1/2}$) of 5-HT uptake (the time taken for the extracellular 5-HT concentration to decrease to half of the peak concentration attained) was used as an (reciprocal) estimate of the rate of 5-HT uptake.

EXPERIMENTAL PROCEDURE

After three stable consecutive 5-HT efflux events were obtained (a control period of 30 min), the agent to be studied (at a concentration of 5 μmol litre^{-1}) was added to the superfusate for 2 h. Five treatment groups were compared: (±)-tramadol, (+)-tramadol, (−)-tramadol, O-desmethyltramadol (M1 metabolite) and control. Controls received aCSF. Group sizes were: (±)-tramadol (n=5 slices), (+)-tramadol (n=6), (−)-tramadol (n=6), O-desmethyltramadol (n=7) and control (n=5).

DRUGS

(±)-Tramadol, (+)-tramadol, (−)-tramadol and O-desmethyltramadol were gifts from Grünenthal GmbH (Germany). Stock solutions of each drug were prepared in distilled water. Subsequent dilutions were made in aCSF.

STATISTICAL ANALYSIS

All drug effects on 5-HT efflux and reuptake were plotted against time. The area under the curve was calculated for each individual experiment and means (SEM) were determined for each series of experiments. The data for (±)-tramadol, (+)-tramadol, (−)-tramadol and O-desmethyltramadol were tested for statistical significance compared with the control group using one-way analysis of variance (ANOVA) with *post hoc* application of Dunnett's test.

Results

Electrical stimulation (20 pulses, 0.1 ms, 100 Hz) in the DRN evoked efflux of 5-HT that was detected at

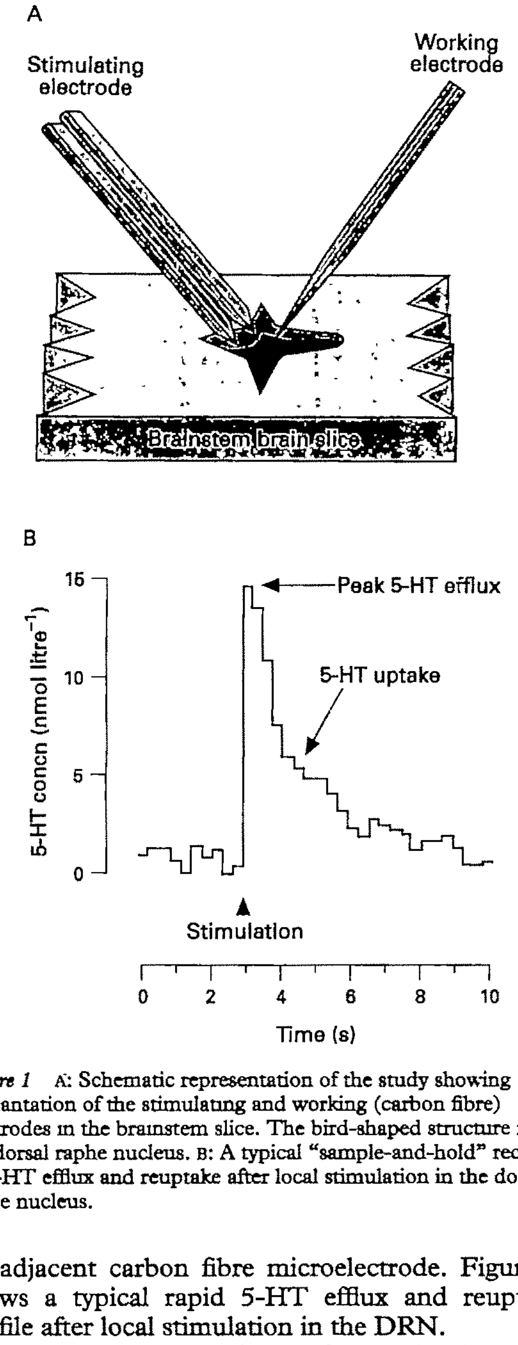

Figure 1 A: Schematic representation of the study showing implantation of the stimulating and working (carbon fibre) electrodes in the brainstem slice. The bird-shaped structure is the dorsal raphe nucleus. B: A typical "sample-and-hold" record of 5-HT efflux and reuptake after local stimulation in the dorsal raphe nucleus.

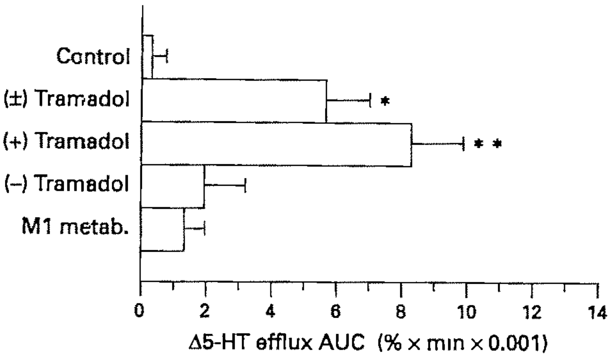

Figure 2 Effects of tramadol, its enantiomers and metabolite on stimulated 5-HT efflux in the rat dorsal raphe nucleus slice. Data are expressed as changes in the area under the 5-HT efflux *vs* time curve, relative to the pre-drug period. All values are mean (SEM) (n=5–7). $^{*}P<0.05$, $^{**}P<0.01$ *vs* control (Dunnett's test).

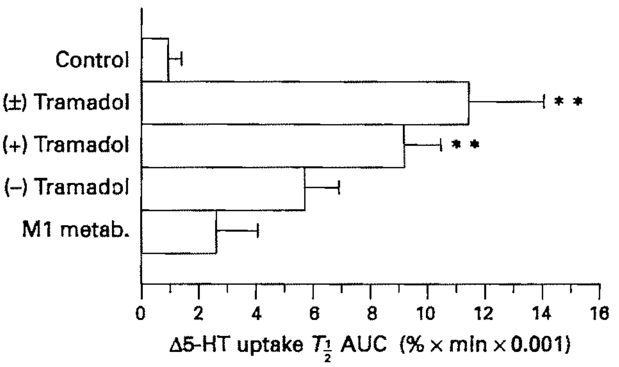

Figure 3 Effects of tramadol, its enantiomers and metabolite on 5-HT uptake half-time ($T_{1/2}$) in the rat dorsal raphe nucleus slice. Data are expressed as changes in the area under the 5-HT uptake $T_{1/2}$ *vs* time curve, relative to the pre-drug period. All values are mean (SEM) (n=5–7). $^{**}P<0.01$ *vs* control (Dunnett's test).

an adjacent carbon fibre microelectrode. Figure 1 shows a typical rapid 5-HT efflux and reuptake profile after local stimulation in the DRN.

Figure 2 shows the effects of tramadol, its enantiomers and main metabolite on stimulated 5-HT efflux. Data are expressed as mean (SEM) post-drug incremental area under the curve. (±)-Tramadol and its (+)-enantiomer significantly increased 5-HT efflux relative to aCSF controls ($P<0.05$ and $P<0.01$, respectively; Dunnett's test). The (−)-enantiomer and O-desmethyltramadol had no significant effect compared with control.

Figure 3 shows the effects of tramadol, its enantiomers and metabolite on 5-HT uptake $T_{1/2}$. As before, data are expressed as mean (SEM) post-drug incremental area under the curve. Similarly, the racemic mixture and (+)-enantiomer significantly slowed 5-HT reuptake (both $P<0.01$ *vs* control; Dunnett's test). O-desmethyltramadol and the (−)-enantiomer were inactive.

Figure 4 shows the time course of the effects of the active drugs, (±)-tramadol and (+)-tramadol, on stimulated 5-HT efflux and uptake $T_{1/2}$. For both (±)-tramadol and (+)-tramadol, there was a temporal dissociation between their effects on 5-HT efflux and uptake. In both cases, the drug effects on 5-HT efflux occurred before changes in 5-HT reuptake $T_{1/2}$.

Discussion

Release of neurotransmitter from isolated tissues maintained *in vitro* has long been a popular means of evaluating monoaminergic uptake mechanisms.[16] However, problems with this technique have been highlighted regarding its applicability to neurotransmitter release within small anatomical regions in the brain. Furthermore, the neurotransmitter pool is frequently labelled with tritium which assumes, probably incorrectly, that release of the radiolabel accurately reflects true neurotransmitter release.[17] We have therefore used FCV at carbon fibre microelectrodes to study the effects of racemic tramadol, its enantiomers and the major human metabolite, O-desmethyltramadol, on *endogenous* 5-HT neurotransmission in the DRN, a key nucleus in the regulation of afferent nociceptive transmission. An FCV scan takes only milliseconds and can be repeated many times per second, thus giving real time detection of neurotransmitter. This high

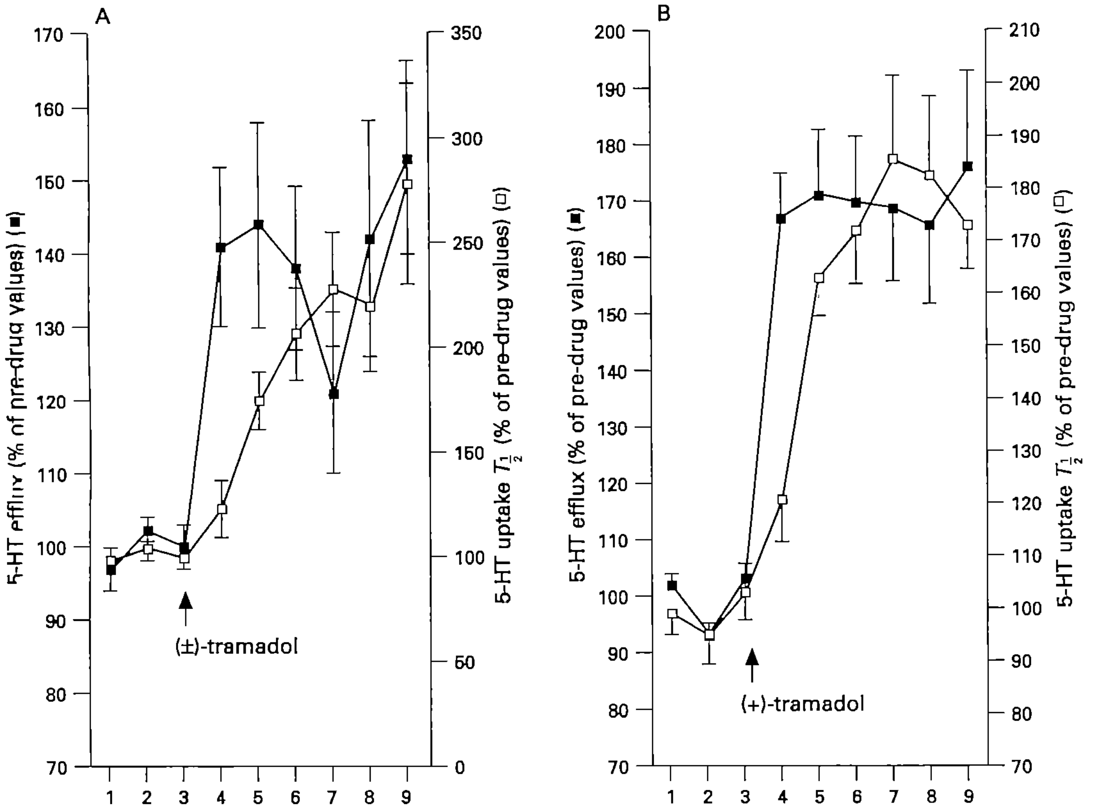

Figure 4 A: Time course of effects of (±)-tramadol 5 μmol litre on stimulated 5-HT efflux and 5-HT uptake half-time ($T_{1/2}$) in the rat dorsal raphe nucleus slice. B: Time course of effects of (+)-tramadol 5 μmol litre on stimulated 5-HT efflux and 5-HT uptake half-time ($T_{1/2}$) in the rat dorsal raphe nucleus slice. All data are mean (SEM) (n=6).

temporal resolution allows the relationship between 5-HT efflux and uptake to be determined precisely (see fig. 1).

In each case the drugs were applied at a concentration of 5 μmol litre^{-1}. This approximates to the plasma concentration of tramadol after a therapeutically effective dose.[18] Both (±)-tramadol and the (+)-enantiomer significantly enhanced stimulated 5-HT efflux in the DRN at this concentration. Neither (−)-tramadol nor the M1 metabolite, O-desmethyltramadol, had any effect (fig. 2). A qualitatively similar picture was obtained for the effects on 5-HT uptake (fig. 3). Again, both the (+)-enantiomer and the racemate were effective while the metabolite was devoid of action. Of interest, (−)-tramadol delayed 5-HT uptake in some slices although the group data were not statistically significant.

These findings are broadly consistent with the literature. Tramadol inhibited 5-HT reuptake, the (+)-enantiomer being the active form.[9] The hint of an effect on uptake with (−)-tramadol also supports the findings of other studies, using synaptosomes and radiolabelled neurotransmitter, indicating that it has approximately 25% of the activity of the (+)-enantiomer on the serotoninergic system.[9]

De-methylation of tramadol resulted in a marked reduction of activity on 5-HT reuptake inhibition. This is interesting for two reasons. First, the M1 metabolite is an effective analgesic and probably contributes significantly to the clinical profile of tramadol[1], presumably via μ opioid receptors.[3] Second, it is clear that the O-methyl function of the parent drug is therefore a structural determinant of 5-HT uptake block by tramadol.

As only those drugs that blocked 5-HT uptake —the (+)-enantiomer and the racemate—also increased 5-HT efflux, there is a prima facie case that uptake block is the *cause* of increased 5-HT efflux. However, such a conclusion is erroneous as the increase in 5-HT efflux after tramadol *preceded* reduced uptake (fig. 4). For both (±)-tramadol and its (+)-enantiomer, the effects on 5-HT efflux were essentially maximal on the first post-drug stimulation. Effects on 5-HT uptake $T_{1/2}$ did not reach maximum until considerably later.

Furthermore, with paroxetine, the effect on 5-HT reuptake is much greater than that on 5-HT efflux because of activation of negative feedback mechanisms reducing efflux.[15] Conversely, the effects of (+)-tramadol on 5-HT efflux and reuptake were of a similar magnitude.

The rapid effect of racemic tramadol and its (+)-enantiomer on 5-HT efflux cannot be caused by 5-HT$_1$ autoreceptor block as the choice of short-duration stimulation variables precludes activation of the autoreceptor during the stimulation train.[19] Furthermore, we have shown previously that the potent 5-HT$_{1A}$ antagonist WAY 100135 did not increase 5-HT efflux in this experimental procedure.[15]

Hence it appears that tramadol may have a direct releasing action. Other studies have shown that the tramadol-induced increase in 5-HT efflux does not occur if 5-HT reuptake sites are blocked by 6-nitroquipazine, before tramadol administration.[9]

This suggests that tramadol can compete with 5-HT for the uptake mechanism and, when inside the presynaptic terminal, increase stimulation-evoked 5-HT release. A direct effect on 5-HT release, dissociated from reuptake inhibition, may be important to the multimodal analgesic actions of tramadol. It is unlikely that opioid receptor activation is responsible for the 5-HT releasing action observed with (+)-tramadol and the racemate as the M1 metabolite had no 5-HT releasing action despite being a more potent opioid than the parent drug.[3]

In conclusion, both racemic tramadol and its (+)-enantiomer blocked DRN 5-HT uptake and increased stimulated 5-HT efflux. The temporal dissociation between these actions suggests that uptake blockade was not the cause of the increased 5-HT efflux and that tramadol might therefore have a direct 5-HT releasing action. It should nevertheless be remembered that we have only examined a single, albeit clinically relevant, concentration of tramadol and it would be interesting to examine such actions over an extended concentration range. Nevertheless, the activity of such mechanisms at clinically pertinent concentrations may help explain the antinociceptive efficacy of tramadol despite weak μ opioid receptor affinity. This study adds to evidence that tramadol exerts actions on central monoaminergic systems and that this mechanism may contribute to its analgesic effect.

Dopamine and intestinal mucosal tissue oxygenation in a porcine model of haemorrhage

R. GERMANN, M. HAISJACKL, B. SCHWARZ, N. SALAK, E. DEUSCH, W. PAJK, H. J. WOLF, B. RIEDMANN AND W. HASIBEDER

Summary

Haemorrhage is associated with intestinal mucosal hypoxia and impaired gut barrier function. Dopamine increases oxygen delivery to the intestinal mucosa and may thus counteract haemorrhage-induced mucosal hypoxia. Jejunal mucosal tissue oxygen tension (mucosal $P\mathrm{o}_2$) and jejunal oxygen saturation of mucosal microvascular haemoglobin (mucosal $\mathrm{Hb}_{\mathrm{O}_2}$) were measured in 14 anaesthetized pigs. Seven animals served as controls (group C) and seven received continuous infusion of dopamine 16 μg kg^{-1} min^{-1} (group D) while 45% of blood volume was removed in three equal increments. Resuscitation was performed using shed blood and fluid. Mean arterial pressure and systemic oxygen delivery decreased significantly during haemorrhage and returned to baseline after resuscitation in both groups. Mucosal $P\mathrm{o}_2$ decreased from 4.4 to 1.7 kPa after haemorrhage ($P<0.01$) and further to 1.5 kPa after resuscitation ($P<0.01$) in group C whereas group D showed an increase from 3.9 to 5.9 kPa after the start of the dopamine infusion ($P<0.05$), but no significant difference from baseline after haemorrhage (2.3 kPa) (ns) or resuscitation (3.1 kPa) (ns). Mucosal $\mathrm{Hb}_{\mathrm{O}_2}$ decreased from 52 to 32% after haemorrhage ($P<0.05$) and increased to near baseline (37%) (ns) after resuscitation in group C whereas group D showed no significant changes from baseline (54 %) throughout the experiment. Comparison between groups showed higher mucosal $P\mathrm{o}_2$ and $\mathrm{Hb}_{\mathrm{O}_2}$ values for group D animals after the start of the dopamine infusion ($P<0.05$ each), after the first two steps of haemorrhage ($P<0.01$ each) and after resuscitation ($P<0.05$ each). We conclude that i.v. dopamine 16 μg kg^{-1} min^{-1} improved tissue oxygenation of the small intestinal mucosa during moderate haemorrhage and subsequent resuscitation. (*Br. J. Anaesth.* 1997; **79**: 357–362).

Sympathetic nervous system, dopamine. Complications, haemorrhage. Gastrointestinal tract, mucosal oxygenation. Pig.

The intestinal vascular response to haemorrhage is characterized by mesenteric arterial vasoconstriction and redistribution of blood flow from the muscularis towards the mucosal layer of the intestinal wall.[1] Despite this autoregulatory escape phenomenon, tissue hypoxia during haemorrhage occurs primarily within the mucosal layer of the intestine.[2] Mucosal tissue hypoxia has been implicated as an important mechanism contributing to haemorrhage-induced mucosal tissue injury, increased mucosal permeability and microbial translocation.[3,4] Dopamine is a known intestinal vasodilator[5] and therefore may counteract haemorrhage-induced intestinal mucosal hypoxia. Recent studies suggest that dopamine may specifically increase mucosal blood flow and tissue oxygenation by redistributing blood flow from the intestinal muscularis and serosa towards mucosa.[6,7] Dopamine has been reported to attenuate the concomitant decrease in mucosal villus blood flow after endotoxin-induced mucosal vasoconstriction,[8] and to increase mucosal tissue $P\mathrm{o}_2$.[9] However, the efficacy of dopamine in preserving intestinal mucosal oxygenation during haemorrhage has never been investigated.

The purpose of this study was to examine the effects of dopamine on small intestinal mucosal oxygenation during stepwise haemorrhage and subsequent resuscitation. Tissue oxygenation was assessed directly using two different and independent measuring techniques: Clark-type surface oxygen electrodes for evaluation of mucosal tissue oxygen tension and tissue reflectance spectrophotometry for determination of oxygen saturation of mucosal microvascular haemoglobin. A pig model was chosen because of the anatomical and physiological similarity of the digestive and cardiovascular systems of swine and humans.[10]

Materials and methods

ANIMAL PREPARATION

The study was approved by the Federal Ministry of Science and Research. Fourteen domestic pigs (33–41 kg) were fasted overnight, but had free access

Accepted for publication. April 3, 1997

to water. The animals were anaesthetized with ketamine hydrochloride 20 mg kg^{-1} i.m., the trachea intubated orally and the lungs ventilated mechanically with a positive end-expiratory pressure of 5 cm H_2O. Tidal volume and ventilatory frequency were adjusted to maintain Pa_{CO_2} at 4.7–5.7 kPa. FI_{O_2} was adjusted to maintain Pa_{O_2} at 13.3–16.0 kPa. Anaesthesia was maintained by continuous infusion of fentanyl 20 µg kg^{-1} h^{-1} and midazolam 0.8 mg kg^{-1} h^{-1}. Neuromuscular block was produced by bolus injections of vecuronium 0.15 mg kg^{-1}.

After induction of anaesthesia the right carotid artery was cannulated for measurement of systemic mean arterial pressure and for blood sampling. A balloon-tip thermodilution pulmonary artery catheter (Baxter Edwards Critical-Care, Irvine, CA, USA) was inserted via the right internal jugular vein for measuring cardiac output and pulmonary artery occlusion pressure, and for mixed venous blood sampling. A separate 14-gauge catheter was inserted via the right internal jugular vein for infusion of dopamine. An 8.5-French gauge catheter was inserted into the left internal jugular vein for withdrawal of 45% of calculated blood volume in three steps.

A midline laparotomy was performed and a small part of the jejunal mucosa exposed by an antimesenteric enterotomy. The boundary of the mucosa was sutured to the oval opening of a cork plate. The intestine was reintroduced into the abdominal cavity with the exception of the exposed mucosa. The mucosal preparation was covered by a humidified Servo-controlled chamber heated to 37°C.

Animals were given Ringer's lactate and gelatine i.v. to maintain pulmonary artery occlusion pressure at 12–14 mm Hg. The infusion was stopped with the beginning of haemorrhage and resumed with re-transfusion of shed blood.

MEASUREMENT TECHNIQUES

Systemic haemodynamics and blood-gas tensions

Arterial, pulmonary artery and central venous pressures were measured using Statham P10EZ pressure transducers (Spectramed-Statham, Bilthoven, The Netherlands). Cardiac output was measured by the thermodilution method, in triplicate, with 10-ml injections of ice-cooled saline. Arterial and mixed venous blood-gas tensions were measured using an AVL automatic blood-gas analyser (AVL Biomedical Instruments, Graz, Austria) and a haemoximeter (OSM2, Radiometer, Copenhagen, Denmark).

Small intestinal mucosal tissue oxygenation

The methodology has been described previously in detail.[11] Briefly, two Clark-type multiwire surface electrodes (Eschweiler, Kiel, Germany) were positioned on the exposed mucosa to record mucosal tissue oxygen tension (mucosal Po_2). A single electrode consists of eight platinum wires, each 15 µm in diameter, representing eight individual measuring points, and a silver–silver chloride reference electrode. The electrodes were kept in place by small polyvinyl chloride caps surrounded by a transparent thin rubber patch with a diameter of 2 cm. During each set of measurements, mucosal Po_2 was recorded continuously for a period of 150 s at a frequency of 1 Hz. An Erlangen microlightguide spectrophotometer (EMPHO II; BGT, Überlingen, Germany) was used to measure oxygen saturation of the mucosal microvascular haemoglobin (mucosal Hb_{O_2}). The spectrophotometer includes one central illuminating microlightguide surrounded by six detecting microlightguides with a diameter of 250 µm each and a rapidly rotating bandpass interference filter disk for generation of monochromated light within the spectral range of 502–628 nm. This filter disk permits sampling in steps of 2 nm and a sampling rate of 100 spectra s^{-1}. Monochromated light is transmitted to a photomultiplier tube operated at current mode, fed into a current-to-voltage converter, and amplified by a cascade amplifier. The voltage signal is offset compensated, filtered by a low-pass filter, fed into an analogue-to-digital converter and transferred to an IBM compatible computer. The algorithm used to calculate oxygen saturation of microvascular haemoglobin has been validated for intestinal mucosal tissue.[11] The microlightguide array was fixed to the mucosal surface in a manner identical to that used for the Po_2 electrode. At each measuring time, 1024 values of mucosal Hb_{O_2} were recorded at a frequency of 7 Hz.

EXPERIMENTAL PROCEDURE (FIG. 1)

After surgical preparation, pigs were allowed to stabilize for 120 min. Pulmonary artery occlusion pressure was maintained at 12–14 mm Hg by infusion of Ringer's lactate and gelatine. At the end

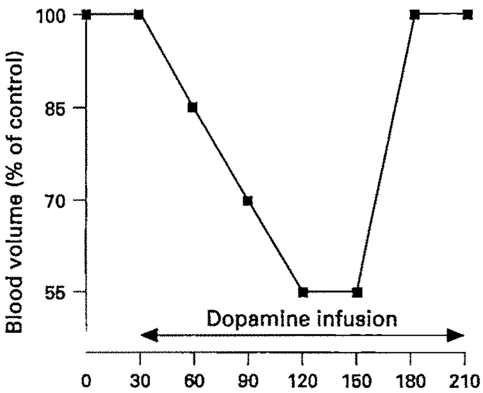

Figure 1 Experimental design. After baseline measurements of haemodynamic and tissue oxygenation variables (t=0 min), seven animals served as controls (group C) and seven animals received continuous infusion of dopamine 16 µg kg^{-1} min^{-1} (group D). In both groups 45% of calculated blood volume was removed in three equal steps. Resuscitation was performed using re-transfusion of shed blood and infusion of fluid in order to restore pulmonary artery occlusion pressure to baseline. Measurements of systemic haemodynamic variables and intestinal mucosal tissue oxygenation were made at 30-min intervals.

of the stabilization period, baseline measurements of haemodynamic state, blood-gas tensions and intestinal tissue oxygenation were performed ($t=0$ min). At this time, animals were allocated randomly to one of two experimental groups: group C ($n=7$) served as controls, whereas group D ($n=7$) received continuous i.v. infusion of dopamine 16 μg kg^{-1} min^{-1} with a concentration of saline 2 mg ml^{-1} (Leopold Inc., Graz, Austria), begining after baseline measurements and continued throughout the experimental period. After a set of measurements at $t=30$ min, infusion of Ringer's lactate and gelatine was stopped in both groups and 45% of calculated blood volume was removed in three equal steps. Measurements of the above variables were repeated after every bleeding step (at $t=60$ min, $t=90$ min and $t=120$ min). After measurements at $t=150$ min, shed blood was re-transfused and infusion of Ringer's lactate and gelatine was resumed in order to restore pulmonary artery occlusion pressure to baseline. Two final measurements were performed at $t=180$ min and $t=210$ min.

At the end of the experiment, animals were killed with a central venous bolus injection of potassium chloride 40 mmol.

STATISTICAL ANALYSIS

Results are expressed as mean (SEM). Comparison between baseline values was made using the unpaired *t* test. Overall effects within and between groups were evaluated by repeated measurement analysis of variance (ANOVA). In the case of significant differences, further comparisons were made with paired *t* tests (within-group to baseline) and unpaired *t* tests (between groups at individual times). $P \leq 0.05$ was considered significant. The Bonferroni–Holm procedure was used for correction of multiple comparisons.

Results

There were no significant differences in baseline systemic variables between group C (no dopamine) and group D (dopamine) (table 1).

Mean arterial pressure, pulmonary artery occlusion pressure and systemic oxygen delivery decreased significantly during stepwise bleeding and returned to baseline after resuscitation in both groups. Systemic oxygen consumption and arterial pH did not change significantly over time in either group. Except for a significant increase after resuscitation in group C animals, arterial packed cell volume (PCV) remained unchanged.

JEJUNAL MUCOSAL TISSUE OXYGENATION (FIGS 2, 3)

There were no significant differences in baseline mucosal tissue oxygen tension (mucosal Po_2; fig. 2) and oxygen saturation of mucosal microvascular haemoglobin (mucosal Hb_{O_2}; fig. 3) between the two groups.

In group C animals, mucosal Po_2 decreased progressively from 4.39 (0.37) kPa at baseline to 1.75 (0.20) kPa after stepwise bleeding ($t=150$ min) ($P<0.01$) and further to 1.45 (0.47) kPa after resuscitation with shed blood and fluid ($t=210$ min) ($P<0.01$). In group D animals, mucosal Po_2 increased from 3.85 (0.48) to 5.87 (0.52) kPa after starting dopamine ($t=30$ min) ($P<0.05$), decreased to 2.32 (0.45) kPa after bleeding ($t=150$ min)—which was not significantly different from baseline—and increased again to 3.09 (0.57) kPa after resuscitation ($t=210$ min). Comparison between groups showed that mucosal Po_2 was higher in group D animals after the start of the dopamine infusion ($t=30$ min) ($P<0.05$), after the first two steps of bleeding ($t=60$ and 90 min) ($P<0.01$ each) and after resuscitation ($t=210$ min) ($P<0.05$).

Table 1 Changes in systemic variables in animals treated without (group C) and with dopamine (group D) during stepwise bleeding ($t=60$, 90, 120 min), after bleeding ($t=150$ min) and after resuscitation ($t=180$, 210 min). Baseline is $t=0$ min. Dopamine infusion was started after baseline in group D animals. MAP=Mean arterial pressure; PAOP=pulmonary artery occlusion pressure; Do_2=systemic oxygen delivery; $\dot{V}o_2$=systemic oxygen consumption; pH_a=arterial pH; PCV=packed cell volume. Values are mean (SEM). *$P<0.05$, **$P<0.01$ *vs* baseline (paired *t* test)

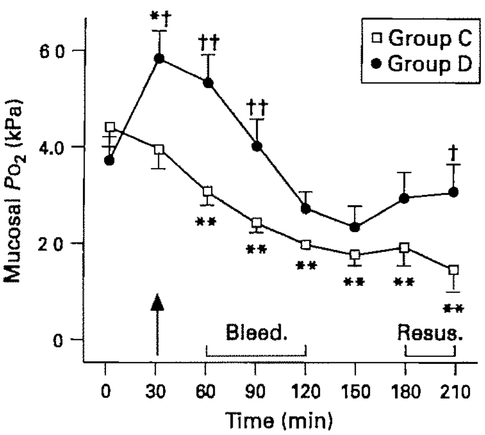

Figure 2 Changes in mucosal tissue $P\text{O}_2$ in animals treated without (group C) and with (group D) dopamine, during and after stepwise bleeding (Bleed.) and resuscitation (Resus.). Baseline is t=0 min. Dopamine infusion was started after baseline in group D animals (arrow). Values are mean (SEM). *$P<0.05$, **$P<0.01$ *vs* baseline (paired t test); †$P<0.05$, ††$P<0.05$ *vs* group C (unpaired t test).

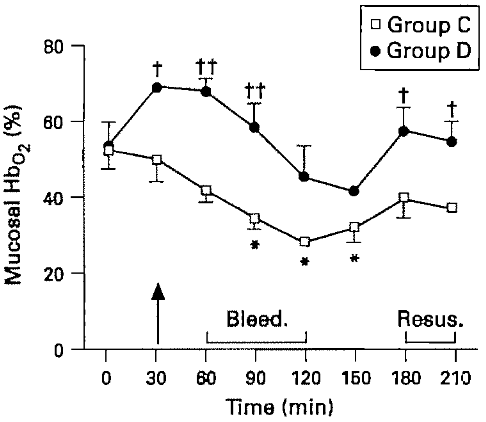

Figure 3 Changes in oxygen saturation of mucosal microvascular haemoglobin (mucosal Hb_{O_2}) in animals treated without (group C) and with (group D) dopamine during and after stepwise bleeding (Bleed.) and resuscitation (Resus.). Baseline is t=0 min. Dopamine infusion was started after baseline in group D animals (arrow). Values are mean (SEM). *$P<0.05$ *vs* baseline (paired t test); †$P<0.05$, ††$P<0.05$ *vs* group C (unpaired t test).

In group C animals, mucosal Hb_{O_2} decreased from 52 (5) % to 32 (4) % after haemorrhage (t=150 min) ($P<0.05$) and increased to 37 (2) % after resuscitation (t=210 min) (ns). In group D animals, mucosal Hb_{O_2} was never significantly different from baseline, despite an increase from 54 (6) % to 69 (1) % after the start of dopamine (t=30 min), a decrease to 50 (8) % after haemorrhage (t=150 min) and an increase to 55 (5) % after resuscitation (t=210 min). Comparison between groups showed that mucosal Hb_{O_2} was higher in group D animals after the start of the dopamine infusion (t=30 min) ($P<0.05$), after the first two steps of haemorrhage (t=60 and 90 min, $P<0.01$ each) and after resuscitation (t=180 and 210 min, $P<0.05$ each).

Discussion

HAEMORRHAGE AND SMALL INTESTINAL MUCOSAL TISSUE OXYGENATION

In this study stepwise loss of 45% total blood volume progressively reduced small intestinal mucosal tissue oxygenation in the pig (figs 2, 3). Spectrophotometrically determined mucosal Hb_{O_2} reflects oxygen delivery to the mucosal and, to a lesser extent, the submucosal layer of the intestinal wall[12] and has been shown to be related linearly to changes in mucosal blood flow during bleeding.[13] The 39% reduction observed at the end of the bleeding period in this study is similar in magnitude to declines in mucosal Hb_{O_2} and blood flow in comparable haemorrhage models.[14 15] This is the first study to measure mucosal tissue $P\text{O}_2$ within the small intestine during bleeding. Clark-type surface $P\text{O}_2$ electrodes appear to be specifically suitable for monitoring tissue oxygenation of the small intestine, as their catchment volume is limited to the villus tip area.[16] The villus tip is thought to be preferentially susceptible to tissue hypoxia during haemorrhage or other intestinal low-flow conditions,[4] because tissue $P\text{O}_2$ is considerably lower at the villus tip than at the base, already under resting conditions.[17] This $P\text{O}_2$ gradient is enlarged during reductions in mucosal blood flow.[18] Thus critically low tissue $P\text{O}_2$ values first appear at the villus tip. In these experiments, mucosal $P\text{O}_2$ was reduced by 60% of baseline values after haemorrhage and thus was more pronounced than total mucosal oxygen delivery, as measured by mucosal Hb_{O_2}. In contrast with mucosal Hb_{O_2}, mucosal $P\text{O}_2$ did not recover after resuscitation with shed blood and fluid even though arterial pressure and systemic oxygen delivery returned to prehaemorrhagic values (table 1). Therefore, decreased tissue oxygenation persisted mainly within the villus tip area. This finding is in accordance with the morphological observation of villus tip injury after resuscitated haemorrhage.[3]

DOPAMINE AND MUCOSAL TISSUE OXYGENATION

Infusion of dopamine 16 μg kg^{-1} min^{-1} increased mucosal $P\text{O}_2$ and mucosal Hb_{O_2} above baseline values in this pig model, although only changes in mucosal $P\text{O}_2$ were statistically significant (group D animals, figs 2, 3; t=30 min). This observation is in agreement with previous findings where i.v. infusion of dopamine 2–32 μg kg^{-1} min^{-1} enhanced jejunal mucosal $P\text{O}_2$ and Hb_{O_2} in a dose-related manner but did not change jejunal serosal $P\text{O}_2$.[7] Similarly, in cats, dopamine 10–25 μg kg^{-1} min^{-1} increased jejunal blood flow to the mucosa and submucosa, whereas muscularis and serosal blood flow decreased slightly.[6] In contrast, intra-arterial infusion of dopamine 0.1 and 0.5 μg kg^{-1} min^{-1} into the superior mesenteric artery of dogs has been reported to increase total mesenteric blood flow but to decrease mucosal blood flow as measured by radioiodine absorption from the gut lumen.[19] However, the results obtained were only descriptive, as the sample size of two dogs at each dose did not allow statistical analysis. Thus the majority of experimental data suggests that dopamine selectively improves intestinal mucosal blood flow and tissue oxygenation. Mucosal vasodilatation seems to be mediated mainly by stimulation of postsynaptic vascular DA_1 receptors, as blockade of these receptors by specific antagonists prevents vasodilatation to a considerable extent,[20] and DA_1 specific agonists such as fenoldopam increase mucosal P_{O_2} which is similar to dopamine.[21]

Dopamine-mediated mucosal vasodilatation maintained tissue oxygenation near baseline after withdrawal of 30% of total blood volume in this study (figs 2, 3; $t=60$ and 90 min), demonstrating that dopamine was effective in improving tissue oxygenation during moderate levels of haemorrhage. However, during and after the last step of bleeding, where volume of shed blood was increased to 45% of total blood volume, mucosal P_{O_2} and Hb_{O_2} decreased to similar absolute values in both groups and a significant difference between the groups was no longer observed (figs 2, 3; $t=120$ and 150 min). The intestinal vasoconstrictor response induced by haemorrhage is mediated by stimulation of the sympathoadrenal and renin–angiotensin system and is largely dependent on volume of shed blood.[22] Hence, when blood loss exceeds 30% of total blood volume, dopamine is no longer effective in competing with the pronounced vasoconstrictor stimulus. A marked difference between the two groups was observed after resuscitation (figs 2, 3; $t=180$ and 210 min); while mucosal tissue P_{O_2} remained significantly decreased in group C animals and reached minimum values at the end of the observation period, recovery to near baseline was observed in group D animals. Mucosal Hb_{O_2} was also significantly higher in group D than in group C animals after resuscitation. Therefore, intestinal mucosal tissue oxygenation could be restored completely in dopamine-treated animals, whereas depressed tissue oxygenation persisted in controls, especially within the villus tip area. It should be noted that dopamine may have improved mucosal blood flow and tissue oxygenation by increasing perfusion pressure within the superior mesenteric circulation in addition to regional vasodilatation. However, this latter mechanism seems unlikely to have occurred in these experiments as arterial pressure did not differ between groups (table 1).

CLINICAL RELEVANCE AND LIMITATIONS OF THE STUDY

Haemorrhage-induced intestinal mucosal hypoxia has been shown to contribute to impaired gut barrier function in experimental models, as seen by increased mucosal permeability, bacterial translocation and mucosal injury.[3] As alterations in gut barrier function may contribute to the pathophysiological processes leading to multiple organ failure and death in severely ill patients,[23] prevention of intestinal mucosal hypoxia seems to be a valuable therapeutic aim in the clinical setting. Our data suggest that dopamine 16 $\mu g\ kg^{-1}\ min^{-1}$ may be useful in improving intestinal mucosal tissue oxygenation during haemorrhage and subsequent resuscitation. A previous study in the same model demonstrated that an equal dose of dopamine produced a more than four-fold increase in intestinal mucosal tissue P_{O_2} after endotoxin-mediated mucosal vasoconstriction.[9] However, these results should be extrapolated to humans and especially to critically ill patients with great caution. Responses of the peripheral vasculature to dopamine have been shown to vary between different mammals.[24] Studies in dogs suggest that the vasodilator effect of dopamine within the superior mesenteric circulation can be overridden by concurrent stimulation of α adrenoceptors at doses higher than 10 $\mu g\ kg^{-1}\ min^{-1}$.[5 25] Yet, this vasoconstrictor effect in dogs is not representative of other mammals, such as pigs, cats and rabbits, where vasodilatation persists at i.v. doses of 20,[26] 25[6] and 50 $\mu g\ kg^{-1}\ min^{-1}$.[24] In humans, the mesenteric vasoconstrictor threshold is still unknown. Clinical evaluation of whether or not dopamine is suitable to treat intestinal mucosal hypoxia could be facilitated by monitoring techniques measuring mucosal tissue oxygenation. At present the only clinical technique that is thought to provide an estimate of gastrointestinal mucosal perfusion or tissue oxygenation is gastric tonometry,[27] which permits pH calculation of gastric mucosal cells (pH_i). Only one study has examined the effects of dopamine on pH_i in hypotensive patients with hyperdynamic sepsis.[28] That study conflicts with ours as a decrease in pH_i was observed, despite an increase in arterial pressure and systemic oxygen delivery during infusion of dopamine. Although a high mean infusion rate of dopamine 26 $\mu g\ kg^{-1}\ min^{-1}$ was used, it is unlikely that this effect on pH_i was caused by α adrenoceptor-mediated mucosal vasoconstriction, as treatment with noradrenaline, a more potent α adrenoceptor agonist, in the same study caused an increase in pH_i. A different explanation is based on observations that dopaminergic receptors may not be distributed uniformly within the gastrointestinal tract. The proximal portion of isolated human gastroepiploic arteries responded to dopamine with α adrenoceptor-mediated vasoconstriction, whereas the distal epiploic branches responded with DA_1 receptor-mediated vasodilatation.[29] Similarly, after infusion of dopamine 25 $\mu g\ kg^{-1}\ min^{-1}$, vascular resistance in the superior mesenteric artery decreased by 50%, whereas it did not change in the coeliac artery in the cat.[24] Thus vasodilatation mediated by stimulation of dopaminergic receptors may be limited to specific parts of the gastrointestinal tract, leading to redistribution of blood flow and tissue oxygenation within this organ after infusion of dopamine.

In summary, we observed that dopamine improved mucosal tissue oxygenation of the porcine jejunum during moderate haemorrhage and subsequent resuscitation. At present, extrapolation of these results to humans and especially critically ill patients is limited because it is uncertain if the intestinal mucosal vascular response to dopamine infusion is similar in pigs and humans.

Effects of magnesium sulphate on the cardiovascular system, coronary circulation and myocardial metabolism in anaesthetized dogs

Y. NAKAIGAWA, S. AKAZAWA, R. SHIMIZU, R. ISHII, S. IKENO, S. INOUE AND R. YAMATO

Summary

We have studied the effects of i.v. bolus doses of magnesium sulphate ($MgSO_4$) 60, 90 and 120 mg kg^{-1} on haemodynamic state, the coronary circulation and myocardial metabolism in nine dogs anaesthetized with pentobarbitone and fentanyl. $MgSO_4$ produced dose-dependent decreases in arterial pressure, heart rate, left ventricular dP/dtmax and left ventricular minute work index (LVMWI) and an increase in the time constant of left ventricular isovolumic relaxation. Stroke volume increased, systemic vascular resistance decreased and cardiac output did not change significantly. $MgSO_4$ produced decreases in coronary perfusion pressure, coronary vascular resistance and myocardial oxygen consumption ($M\dot{V}O_2$). Coronary sinus blood flow, lactate extraction ratio and the ratio of LVMWI to myocardial $M\dot{V}O_2$, that is an index of cardiac efficiency, did not change significantly. This study indicated that the depressant effect of $MgSO_4$ on cardiac function was offset by lowering of peripheral vascular resistance, so that cardiac pump function remained effective, and the almost constant coronary sinus blood flow resulted from the decrease in coronary vascular resistance even at higher doses. (*Br. J. Anaesth.* 1997; **79**: 363–368).

Key words
Hypnotics barbiturate, pentobarbitone. Cardiovascular system, effects. Heart, metabolism. Pharmacology, magnesium sulphate. Dog.

Magnesium sulphate has been used for decades in the management of eclampsia[1 2] and pregnancy-induced hypertension.[3 4] Recent reports on magnesium have emphasized its role in deficiency syndromes,[5–7] including cardiac arrhythmias.[8 9 10] The therapeutic importance and physiological roles of magnesium have been summarized by Iseri and French,[11] and an extensive review on clinical experiences has been published by James.[12]

The evidence for cardiac depression by clinically useful concentrations of hypermagnesaemia is less clear, despite its wide clinical use. Some authors have demonstrated that there is no evidence of myocardial depression at any concentration of serum magnesium,[13] whereas others have reported that a single injection of magnesium sulphate leads to a decrease in cardiac performance.[14] Although the cardiovascular haemodynamic effects of magnesium sulphate were assessed by some authors in baboons,[13] sheep[15] and humans,[16] there have been few reports on magnesium-induced changes in left ventricular diastolic function. The effects of magnesium sulphate on the coronary circulation and myocardial metabolism have not been studied extensively.

This study was designed to investigate the effects of magnesium sulphate on haemodynamic state, including left ventricular diastolic function, coronary circulation and myocardial metabolism, in open-chest dogs.

Materials and methods

The study was approved by the management committee at Jichi Medical Laboratory of Experimental Medicine, based on the school's Guide for Laboratory Animals, 1993.

Nine mongrel dogs (mean weight 23.5 (range 18–30.5) kg) were anaesthetized with pentobarbitone 30 mg kg^{-1}. After tracheal intubation, the lungs were ventilated with a Harvard pump respirator ($F\text{I}_{O_2}=1.0$). Arterial carbon dioxide tension was maintained at 4.8–5.3 kPa, as assessed by continuous measurement of end-tidal carbon dioxide concentration with a calibrated respiratory gas monitor (Model 5250, Ohmeda, Madison, WI.,USA) and repetitive analyses of arterial blood-gas tensions. Temperature was measured with an oesophageal thermistor and maintained at 36–37 °C using an external heating pad. Anaesthesia was maintained during surgery with fentanyl 20 μg kg^{-1} h^{-1} and 0.5–2.0% sevoflurane in pure oxygen. All animals were paralysed with bolus doses of pancuronium 0.2 mg kg^{-1} followed by small doses as needed.

Heart rate (HR) was monitored by electrocardiography (ECG, lead II), and systolic, diastolic and

mean arterial pressures (SAP, DAP and MAP, respectively) were measured with a micromanometer-tipped catheter (7F 45326, Toyoda, Ltd, Tokyo, Japan) placed via the left femoral artery into the abdominal aorta. A catheter was placed in the abdominal aorta via the right femoral artery for arterial blood sampling. Lactated Ringer's solution was infused at 5–10 ml kg^{-1} h^{-1} into the right femoral vein throughout the experiment.

After median sternotomy, an appropriately sized electromagnetic flow transducer (FB-140T, Nihon Kohden, Ltd, Tokyo, Japan) was placed around the root of the ascending aorta and connected to a flowmeter (MFW2100, Nihon Kohden, Ltd, Tokyo, Japan) for measurement of ascending aortic flow and cardiac output (CO). A micro-tip catheter (8F PC380, Millar, Inc.) was inserted through a stab wound in the apex of the left ventricle for measurements of left ventricular pressure (LVP) and left ventricular end-diastolic pressure (LVEDP). The rate of increase of left ventricular pressure (LVd*P*/d*t*) was obtained with an analogue differentiating circuit incorporated with an analogue-to-digital converter (Contractility Unit 1323, NEC San-ei, Ltd, Tokyo, Japan) and used as an index of left ventricular contractile function. Coronary sinus blood flow (CSBF) was measured by the retrograde thermodilution technique with a catheter (Thermoflow CCS-7U-90A, Webster Labs., Inc.) inserted into the coronary sinus via the right auricle.[17] Cold normal saline as the indicator was infused at 20 ml min^{-1} for 20 s with an infusion pump (SW-367, Sage Inst., Inc.) through the catheter for each measurement of CSBF. A pair of piezoelectric crystals (5 MHz, Sonotek Co., San Diego, CA, USA) were inserted into the subendocardium in the anterior and posterior walls of the left ventricle and connected to an amplifier (amplifier Unit 4105, NEC San-ei., Ltd, Tokyo, Japan) for measurement of left ventricular end-diastolic and end-systolic diameters (LVEDD and LVESD). Fractional shortening (FS) was obtained using the following formula and used as an index of left ventricular contractile function: FS= (LVEDD−LVESD)/LVEDD×100. All variables were recorded continuously on a polygraph (RECTI-HORIZ-8K23, NEC San-ei, Ltd, Tokyo, Japan).

Arterial and coronary sinus blood was sampled simultaneously to measure pH, P_{O_2}, P_{CO_2}, base excess, standard bicarbonate and haemoglobin concentrations (288 Blood Gas System, Ciba Corning), lactate, non-esterified fatty acid (NEFA) and magnesium concentrations. Lactate concentrations were measured using an enzymatic method. Myocardial oxygen consumption ($M\dot{V}O_2$), the ratio of left ventricular minute work index to $M\dot{V}O_2$ (LVMWI/$M\dot{V}O_2$), myocardial oxygen extraction ratio (MO_2ext.), myocardial lactate extraction ratio (MLext.) and myocardial non-esterified fatty acid extraction ratio (MNEFAext.) were calculated. All derived variables and their abbreviations are shown in table 1.

Left ventricular pressure (LVP), LVd*P*/d*t*, LVEDP and ECG signals were fed to a multichannel photographic oscillograph (Visigraph 5137, NEC San-ei Inst., Ltd, Tokyo, Japan) and recorded at a paper speed of 500 mm s^{-1} to obtain the time constant of left ventricular isovolumic relaxation (*T*). *T* was calculated according to the method of Weiss, Frederiksen and Weisfeldt[18] and used as an index of left ventricular relaxation.

At the end of the surgical procedure, sevoflurane was discontinued and fentanyl was infused at a rate of 20 μg kg^{-1} h^{-1}. Approximately 30 min was allowed after withdrawal of sevoflurane for stabilization of haemodynamic variables and baseline values were obtained. All dogs were given a 12.3% solution of magnesium sulphate in a bolus dose of 60, 90 and 120 mg kg^{-1} (0.49, 0.73 and 0.98 ml kg^{-1}, respectively) over 10 s at 20-min intervals consecutively. The ratio of osmolarity of magnesium sulphate to that of saline is 3.0 : 1.0. Haemodynamic measurements and blood sampling were performed 1 min before and after each administration of magnesium sulphate.

All values are presented as mean (SEM). Data were analysed statistically using analysis of variance for repeated measurements (ANOVA). Where appropriate, this was followed by the Scheffe *F* test. A probability of chance occurrence less than 5% ($P<0.05$) was considered statistically significant.

Results

Serum concentrations of magnesium 1 min after each bolus administration and the effects on haemodynamic state are shown in table 2. Haemodynamic variables decreased within the first minute and gradually returned to near baseline values after 20 min. Serum concentrations of magnesium before and after administration of magnesium sulphate of 60, 90 and 120 mg kg^{-1} were 1.3 (0.1), 6.3 (0.3), 9.7 (0.5) and 14.4 (0.7) mg dl^{-1}, respectively. Magnesium sulphate produced dose-dependent

decreases in HR, SAP, DAP, MAP, LVMWI and LVd*P*/d*t* max ($P<0.01$). Stroke volume increased significantly but cardiac output did not change significantly (fig. 1). The near constant CO may have been brought about by the decrease in systemic vascular resistance (SVR) (fig. 2). LVEDD, LVESD and FS did not change significantly. *T* increased in a dose-dependent manner, indicating a decrease in left ventricular diastolic function.

The effects of magnesium sulphate on the electrocardiogram are shown in table 3. Magnesium sulphate increased sinus cycle length, PQ and QT intervals dose-dependently ($P<0.01$). QRS duration and corrected QT interval (QTc) increased significantly, but not dose-dependently. P wave, ST segment and T wave configurations did not change significantly. Magnesium sulphate did not produce arrhythmia.

The effects of magnesium sulphate on the coronary circulation and myocardial metabolism are shown in table 4. Magnesium sulphate produced dose-dependent decreases in coronary perfusion pressure (CPP) and $M\dot{V}O_2$ ($P<0.01$). Coronary vascular resistance (CVR) and Mo_2ext. ratio decreased, but not dose-dependently. Any significant changes in CSBF, the ratio of CSBF to CO, MLext. ratio, MNEFAext. ratio and LVMWI/$M\dot{V}O_2$ were not observed at each dose of magnesium sulphate.

Discussion

The major findings of this study were that magnesium sulphate, in a dose-dependent manner, lowered systemic vascular resistance, arterial pressure and heart rate, while cardiac output was well maintained. Cardiac work, derived from both stroke volume and heart rate, and myocardial oxygen consumption, decreased markedly in parallel with systemic vascular resistance. Magnesium sulphate maintained coronary perfusion and cardiac efficiency even at higher doses.

With an unchanged cardiac output, the decrease in arterial pressures must result from a decrease in systemic vascular resistance, which may be caused mainly by the vasodilator effects of magnesium sulphate that have been demonstrated *in vitro*,[19 20] in intact animals[13 21] and in humans.[15] The cardiovascular effects of magnesium are as follows: (1) inhibition of the normal rhythm or vasomotion (spontaneous mechanical activity) of vascular smooth muscle, (2) depression of the contractile responses to endogenous neurohumoral substances that maintain vascular tone,[22] (3) possibly blockade of sympathetic ganglia[23] and (4) negative inotropism.

In humans, Mroczek, Lee and Davidov[15] reported that infusion of magnesium sulphate resulted in a rapid but transient decrease in arterial pressure in hypertensive patients, whereas normotensive subjects did not demonstrate any appreciable change in arterial pressure. McCubbin and co-workers[24] reported cardiopulmonary arrest caused by acute maternal hypermagnesaemia (35.1 mg dl^{-1}). In animals, transient[16] and marked[13 25] hypotension has been reported. This transient hypotension may be explained partially by rapid clearance of magnesium from plasma through the kidney. James, Cork and Dennett[13] demonstrated the difficulties of maintaining high serum magnesium concentrations in the presence of normal renal function. They administered in the baboon a loading dose of 60 mg kg^{-1} over 1 min and then infused continuously 12.5 mg min^{-1} for at least 5 min. The infusion rate was then increased to 25 mg min^{-1} and by 25 mg min^{-1} every 5 min up to a maximum of 200 mg min^{-1}. The maximum serum magnesium concentration attained was only 9.4 mmol $litre^{-1}$. Dandavino and colleagues[16] observed that rapid administration of magnesium sulphate produced hypotension but a more gradual administration did not produce hypotension. In our study, magnesium sulphate at bolus doses of 60, 90 and 120 mg kg^{-1} administered every 20 min produced a dose-dependent decrease in arterial pressure. This decrease in arterial pressure corresponded to increases in serum concentrations of magnesium.

Magnesium sulphate is known to have a negative inotropic action and cause myocardial depression and cardiac arrest in massive doses.[24] In this study, magnesium sulphate produced a dose-dependent decrease in LVd*P*/d*t*max. Although the decrease in LVd*P*/d*t*max can be explained partially by the decrease in heart rate,[26] this indicates that magnesium sulphate exerted a dose-dependent negative inotropic action in the whole animal. Left ventricular pump function, however, was well compensated by the increase in stroke volume caused by the lowering of peripheral vascular resistance. In fact, magnesium sulphate 60 and 90 mg kg^{-1} produced a significant increase in stroke volume despite a marked decrease in LVd*P*/d*t*max. Cardiac output also was maintained well at a high dose of 120 mg kg^{-1}. The profound decrease in heart rate may be the main effect of magnesium sulphate, with the heart compensating by a Starling effect to increase stroke volume appreciably. This finding is consistent with previous reports.[3 13 27] James, Cork and Dennett[13] demonstrated that cardiac output was maintained at control values, at concentrations of serum magnesium greater than 5 mmol $litre^{-1}$. Cotton, Gonik and Dorman[3] and Mroczek, Lee and Davidov[15] also demonstrated that magnesium sulphate produced an increase in cardiac output despite significant myocardial depression. These findings and ours suggest that the direct myocardial depressant effect with magnesium may be compensated by decreased afterload, resulting in the maintenance of cardiac function as a pump. No significant change in fractional shortening as an index of left ventricular systolic function during ejection phase could be attributed to the decrease in afterload.

Some authors[16 25] have reported that tachycardia occurred during administration of magnesium sulphate, whereas others[13] have reported that bradycardia was seen. In our study, magnesium sulphate produced a dose-dependent decrease in heart rate and prolongation of PQ and QTc intervals. The degree and rate of increase of blood magnesium concentration may partially explain the different findings observed among these studies. At a low serum concentration of magnesium, hypotension may produce tachycardia through the baroreflex pathway, whereas at a high concentration bradycardia may be brought about by both indirect and direct inhibitory effects of magnesium on the sinoatrial node. As for indirect inhibitory effects, Stanbury[23] found that magnesium induces a short-lived blockade of the sympathetic ganglia and prevents the stimulating effects of potassium and acetylcholine on the superior cervical ganglion in anaesthetized cats. As for direct inhibitory effect, Opthof and colleagues[28] demonstrated that magnesium itself decreased the rate of diastolic depolarization of the pacemaker cells in the sinus node.

In this study, magnesium sulphate did not produce any arrhythmias or conduction disorders at serum concentrations of 6.3 (0.3) to 14.4 (0.7) mg dl^{-1}, although it produced a dose-dependent decrease in heart rate and prolongation of PQ, QRS and QTc intervals. This finding is consistent with our earlier study[29] except for QTc interval. The difference of basal anaesthesia may be associated with the different results of QTc interval.

Although the effects of magnesium sulphate on systemic haemodynamic state and myocardial contractility have been described in other studies,[13 15 16] the effect on ventricular diastolic function *in vivo* or *in vitro* remains unexplored. In this study, the effect of magnesium sulphate on left ventricular relaxing function was investigated by the time constant of left ventricular isovolumic relaxation (*T*). The shorter the *T* value, the better the relaxing function of the left ventricle, and vice versa.[18] Magnesium sulphate produced a dose-dependent increase in *T* in this study. Therefore, magnesium may depress left ventricular relaxing function. Because *T* tends to increase with a decrease in heart rate and depressed systolic fibre shortening,[18] the decrease in *T* observed here appeared to be related not only to decreased left ventricular relaxing function but also to decreased heart rate and depressed systolic fibre shortening.

The effects of magnesium sulphate on the coronary circulation and myocardial metabolism have not been studied extensively. This study demonstrated that magnesium sulphate did not change coronary sinus blood flow remarkably despite a decrease in coronary perfusion pressure. This suggests that magnesium sulphate may have a coronary vasodilating effect. A dose-dependent decrease in $M\dot{V}O_2$ appeared to parallel the decreased external work of the heart, because LVMWI/$M\dot{V}O_2$ did not change significantly. The decrease in LVMWI is thought to be caused mainly by reduction in arterial pressure. Lactate production was not observed throughout this study. Therefore, magnesium sulphate may maintain an appropriate oxygen supply-and-demand relation in the myocardium and may exert no major adverse effects on cardiac function as a pump.

The findings of this study could be related to basal anaesthesia because of an acute open-chest canine preparation under general anaesthesia. Priebe demonstrated an anaesthetic technique comprising pentobarbitone, with fentanyl maintaining a stable, global haemodynamic state over a prolonged period.[30] Cox[31] demonstrated that haemodynamic variables returned to control levels within 15 min after pentobarbitone 30 mg kg^{-1} i.v. in dogs, although heart rate remained increased from the control value of 85 beat min^{-1} to 132 beat min^{-1} even after 60 min. In this study, however, a heart rate of 125 (5) beat min^{-1} immediately after administration of pentobarbitone decreased to a baseline value of 109 (8) beat min^{-1} immediately before initiation of measurements.

The osmolarity of magnesium sulphate solutions used could not produce any transient cardiovascular effects because the volumes were small and osmolarity might be lowered by the circulating blood of the dogs.

Magnesium sulphate competes with calcium at the cell membrane and is regarded in many clinical situations as a physiological calcium blocker. This concept may be supported by the facts that magnesium sulphate (1) exerted a mild consistent, dose-dependent hypotensive effect, (2) preserved cardiac pump and coronary sinus blood flow despite a decrease in coronary perfusion pressure, (3) produced negative inotropic effect, (4) decreased myocardial oxygen consumption and (5) did not produce arrhythmia. These effects are thought to be beneficial for patients with ischaemic heart disease.

In future, magnesium will be used more widely in many medical situations, including anaesthetic practice as a physiological calcium blocker.

REVIEW ARTICLE

Pain after laparoscopy

J. I. ALEXANDER

Laparoscopy (Greek λαπαρα—flank, or λαπαροσ—soft; σκοπηιν—to look) involves insufflation of the abdomen by gas or other fluid so that the endoscope (usually 6–10 mm in diameter) can view the intra-abdominal contents without being in direct contact with the viscera or tissues. Surgical procedures can be carried out by instruments introduced through one or more additional ports. Laparoscopy therefore defines the surgical approach and is associated with pain which is additional to that caused by intra-abdominal trauma. Nevertheless, pain which occurs after this procedure is significantly less and shorter than that caused by the same surgical procedure made possible by laparotomy.[7,45,50,65,90] The total costs of the procedure are less[32] and the long-term morbidity is less than when performed by laparotomy.[88] The reduction in both pain and loss of function has made possible earlier discharge from hospital,[64] provided that control of residual pain is not by drugs which also prevent discharge because of nausea, ileus or reduction of consciousness and autonomous function.[70,99] Early discharge also reduces the safety of powerful analgesics and makes difficult monitoring and adequate treatment of pain after laparoscopy.

Timing and pattern of pain after laparoscopy

Pain may occur in the upper abdomen, lower abdomen, back or shoulders. It may be transient or persist for at least 3 days.[26,79] Shoulder pain may occur in as many as 63%[78] or as few as 35% of patients.[26] The incidence is not altered if suxamethonium is used to facilitate tracheal intubation.[98] The greatest incidence of pain is in the upper abdomen.[26] Reporting of pain (at any site) is greatest after operation, decreases to a low level within 24 h, but increases to a second or even a third peak later.[2,4,26] Joris and colleagues[46] reported that after laparoscopic cholecystectomy, visceral pain predominates in the first 24 h but subsides from a peak soon after operation, whereas shoulder pain, minor on the first day, increases and becomes significant on the following day.

Mechanism of pain after laparoscopy

This has been reviewed by Schoeffler, Diemunsch and Fourgeaud.[81] Rapid distension of the peritoneum may be associated with tearing of blood vessels, traumatic traction of the nerves and release of inflammatory mediators. The prolonged presence of shoulder tip pain[26,45,78] suggests excitation of the phrenic nerve. This pain is present often after laparotomy[65] and both laparotomy and laparoscopy are associated with persistent pneumoperitoneum, sometimes for 3 days. There is a statistically significant correlation between the width of the gas bubble and pain score,[42] and this pain can be reduced by aspiration of the gas under the diaphragm,[78] by "active aspiration", that is repeated suction and manipulation,[30] by the use of a gas drain [2] or by application of local anaesthesia under the diaphragm under direct vision[71,73] or through a sub-phrenic catheter.[34] Peritoneal inflammation or the presence of gas is probably also the origin of the upper abdominal pain after lower abdominal surgery or after diagnostic laparoscopy. This also can persist for at least 3 days.[26] The use of nitrous oxide instead of carbon dioxide for peritoneal insufflation may not be responsible for the intra-abdominal explosions reported,[41] but it alters insignificantly the incidence and severity of postoperative pain or nausea and vomiting.[43,55] Comyn[18] reported that peritoneal biopsy performed 2–3 days after laparoscopy showed peritoneal inflammation and neuronal rupture, and there was a linear inverse relationship between abdominal compliance at the time of laparoscopy and severity of postoperative pain. Suxamethonium may be used to facilitate intubation and its use can be associated with pain across the shoulders, but its avoidance is not associated with a reduction of pain in the shoulders.[98]

PAIN AFTER LAPAROSCOPIC STERILIZATION

Laparoscopic sterilization is probably the most common operation by laparoscopy in the UK. It is more painful than diagnostic laparoscopy.[29,39] Davis and Millar[23] showed that laparoscopic sterilization pain was worse than that after diagnostic

laparoscopy for the first 4 h after operation but was not significantly greater after hospital discharge on the same day as surgery. Analgesia tends to be given more readily during studies of pain or analgesics than at other times so that the incidence of pain after laparoscopic tubal occlusion is difficult to judge from published studies. In some placebo-controlled studies of postoperative analgesics, some of the patients in the control groups did not receive additional analgesia (see Larsen and Jensen[52]). Nearly all, however, had received some form of intraoperative analgesia.

The three methods of tubal ligation commonly used are diathermy, ring or loop occlusion and clips (e.g. Hulka or Filshie). There is considerable difference in the amount of lower abdominal pain between the methods. Chi and Cole[14] found more pain both during the procedure (under local anaesthesia) and after operation when rings were used than when spring-loaded clips were used. Dobbs and colleagues[26] found that the incidence and severity of lower abdominal pain were significantly higher after ring sterilization than after Hulka clip sterilization and that the pain after clip sterilization did not differ significantly from that after diagnostic laparoscopy . The greatest difference was in lower abdominal pain in the first 6 h after operation. Huang and colleagues[40] found that, under local anaesthesia, tubal diathermy caused more pain than Falope rings but that after 4 h the pain after rings exceeded that of diathermy. Lawson, Cole and Templeton[53] (and Leggat and Barr[54] retrospectively) found that Falope rings were associated with administration of more analgesics than electrocoagulation (diathermy). Comfort and colleagues[17] found that the pain of clips exceeded that after diathermy and others also noted the similarity in character and distribution of colicky pain at and after sterilization with that of dysmenorrhoea.[40]

Pain relief

LOCAL ANAESTHESIA

Pain after diagnostic laparoscopy can be reduced significantly by a bilateral rectus sheath block, performed above the umbilicus with approximately 15 ml of 0.25% bupivacaine on each side.[86]

The pain that follows tubal ligation can be lessened by application of local anaesthetic directly to the fallopian tube or by injection into the mesosalpinx[1 72 85] at operation. This has been shown to have an effect after rings or bands, but also after fulguration or even when applied at the same time, as a gel, as the Filshie clip.[6 48 60 62 75] McKenzie and colleagues[61] reported that 1% etidocaine, when applied to the fallopian tubes from the uterus to the fimbriae, was superior to 0.75% bupivacaine. Its use led to reduced postoperative use of morphine and fewer admissions to hospital overnight.

The total pain of laparoscopy can be reduced by application of local anaesthesia under the diaphragm under direct vision,[73] through an irrigation device[38] or through a sub-phrenic catheter.[34] Shoulder pain after pelvic peritonoscopy can be reduced by either lignocaine or bupivacaine i.p.,[57] and the addition of adrenaline[71] permitted a large volume to be used without approaching systemic toxicity.[87] Conversely, local anaesthetics administered i.p. seem to be ineffective for either visceral or shoulder pain after laparoscopic cholecystectomy[46 77 80] but these studies did not document a head-down tilt to bathe the tissues supplied by the phrenic nerve. However, Schulte-Steinberg and colleagues[82] found that a single injection of interpleural 0.25% bupivacaine 30 ml, but not interpleural morphine 1.5 mg, morphine 1.0 mg i.p. or 0.25% bupivacaine 20 ml i.p., significantly reduced the global pain after laparoscopic cholecystectomy for 6 h in a randomized, double-blind, saline-controlled study of 110 patients. The intraperitoneal drugs were sprayed under pressure over the gallbladder bed and the diaphragmatic surface of the liver. This did not greatly affect the pain perceived in the shoulders. Of patients who received a peritoneal injection, seven of 50 complained of shoulder pain at 6 h, and 24 complained at 24 h. Of those who received interpleural injections, seven of 60 reported shoulder pain at 6 h, and 23 at 24 h. Those reporting shoulder pain were distributed evenly between the treatment and control groups. However, Chundrigar and colleagues,[15] using 20 ml of 0.25% bupivacaine directly onto the gallbladder bed, reported significant pain relief.

Pelvic laparoscopy can be performed under spinal anaesthesia alone, either intrathecally[84] or extradurally,[31] and, in an uncontrolled cohort, caudal extradural anaesthesia provided effective pain relief in children after laparoscopic transperitoneal herniorrhaphy.[91]

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

The amount of pelvic pain after tubal manipulation or tubal ligation may be related to concentrations of prostaglandins. Prostaglandin concentrations are known to increase with dysmenorrhoea. Prostaglandin $PGF_{2\alpha}$ is found in the human oviduct at 10 times the concentration found in plasma. Its localization changes at the time of ovulation. $PGF_{2\alpha}$ is found mainly in the isthmus and correlates with motility of this region, whereas PGE_1 is found in the ampulla.[13 74 94] The human ovarian follicle contains both PGE_2 and $PGF_{2\alpha}$ in critical amounts. Laparoscopic tubal manipulation and ligation release prostaglandins, which may increase the frequency of nociceptive impulses and cause pain. This pain may therefore be amenable to prostaglandin synthase inhibitors. Rarely however, is lower abdominal pain assessed separately from upper abdominal, chest or shoulder pain. Even when it is, pain scores and re-medication may be used for the global pain experience.[2 19 98]

EFFICACY OF NON-STEROIDAL ANTI-INFLAMMATORY DRUGS (NSAID)

The prospective, randomized, controlled comparisons of NSAID with placebo which showed that NSAID were superior to placebo in reducing pain or reducing

the requirement for additional analgesic after laparoscopy are shown in table 1. Those which showed no significant benefit of NSAID compared with placebo are shown in table 2.

COMPARISON OF NSAID WITH OTHER ANALGESICS FOR THE PAIN AFTER PELVIC LAPAROSCOPY

Randomized, controlled comparisons of NSAID with other analgesics are shown in table 3. NSAID have been compared with paracetamol, codeine, oxycodone, fentanyl, morphine, pethidine, dexmedetomidine and dezocine.

Comparison with paracetamol[40] showed that meclofenamate was more effective in reducing the pain of tubal ligation during and after local anaesthesia, although both drugs were insufficient in most cases. However, both drugs were given 1 h before operation and peak concentrations of oral paracetamol were achieved at approximately 1 h in plasma and at 4 h in CSF,[5] so that maximal analgesia would not have been achieved at the time of surgery.

Dexmedetomidine was effective in reducing the need for other analgesia but was distinguished by increased somnolence and bradycardia, such that 33% of such subjects required atropine.[3] Dezocine was associated with a higher incidence of nausea or vomiting (60%) than either ketorolac or fentanyl, and most of the dezocine subjects required antiemetic therapy.[25] In a comparison of zomepirac 100 mg with codeine 60 mg[27] for the pain of sterilization with diathermy or rings, there was little difference in pain intensity or additional opioid requirements. Zomepirac has since been withdrawn because of the incidence of NSAID-related side effects. Ketorolac 30 mg i.m. has been compared with pethidine 100 mg i.m. after induction of anaesthesia.[11] Duration of operation was not stated, but at 30 min after operation those who had received pethidine had only marginally less pain, at 1 h there was no difference, and at 4 h after operation the

ketorolac group had significantly less pain than the pethidine group.

Both of these groups were given fentanyl during operation and this technique was used in a large minority of the comparisons.[11 25 35 58] When fentanyl was given during operation, either as a single bolus or as cardiovascular changes indicated, and sufficient time elapsed before assessment of analgesia, ketorolac[25 58] reduced postoperative pain more than fentanyl alone. When NSAID were the sole analgesics for sterilization, they were less effective than morphine[22] or oxycodone.[3] For diagnostic laparoscopy without sterilization, ibuprofen and fentanyl were equally effective.[79] In a double-blind, double-dummy study of 80 patients undergoing sterilization with Falope rings, diclofenac i.m. was compared with fentanyl i.v.[35] At approximately 40 min after administration of diclofenac and 30 min after fentanyl, less pain was associated with fentanyl. However, 30 min later, in those requesting additional analgesia, the fentanyl group reported more pain. Perhaps more significantly, most pain scores in the first 2 h after operation were unsatisfactorily high (authors' own comment) and the scores of those who requested additional analgesia were not always higher than those who did not. The time to the first analgesic, when given, was also similar in both groups.

These results suggest that NSAID in usual therapeutic doses are more effective than paracetamol. They also suggest that analgesia associated with NSAID was broadly similar to that of short-acting opioids such as pethidine or fentanyl provided that the assessment is made around the peak action of the NSAID or at the end of the duration of action of the opioid. The combination of an NSAID and a short-acting opioid is more effective in intensity and duration than the short-acting opioid alone. However, comparisons of diclofenac with oxycodone and fenoprofen with morphine showed that the longer-acting opioid was clinically significantly more effective.

NSAID AND POST-LAPAROSCOPIC CHOLECYSTECTOMY PAIN

Wilson and colleagues[95] investigated diclofenac 75 mg i.m. at induction of anaesthesia compared with placebo. Intraoperative fentanyl 3 μg kg^{-1}, with supplements as required, was used in all patients. A second dose of the drug was given after 12 h and morphine was given as required. Pain was scored on a visual analogue scale at 4, 24 and 48 h after operation. In the diclofenac group, pain was significantly less at 4 h and there was a lower consumption of morphine (ns).

Liu and colleagues[56] gave ketorolac 30 mg, 15 min before induction, another 30 mg after intubation and 60 mg 4 h after operation, and compared ventilatory, recovery and analgesic effects with saline. Duration of anaesthesia was approximately 2 h. Significantly lower pain scores were recorded in the ketorolac group. One-third of the ketorolac group and two-thirds of the saline group required additional post-operative analgesia. There was no significant difference in anxiety, sedation or nausea between the two groups. There was also no difference in the severity of ventilatory dysfunction.

The undisputed success of NSAID in this operation relative to pelvic laparoscopy may be because the pain was relatively more dependent on inflammatory mediators, because the operation was longer and more intraoperative analgesics were given, or because there was a longer time from administration to assessment of the NSAID.

FAILURE OF NSAID TO PROVIDE MORE PAIN RELIEF THAN PLACEBO

There appears to be wide variation in efficacy of NSAID on pain after laparoscopy. Some randomized, double-blind, controlled studies showed insignificant effects, although none suggested that NSAID were less effective than placebo. This lack of efficacy is contrary to the numerous studies which demonstrate a convincing analgesic effect or opioid-sparing effect of NSAID for the pain of more invasive surgery[12 20 69 92] in which pain scores were used and opioid use was measured by patient-controlled analgesic administration.

MacLennan and colleagues[63] showed that there is an insignificant reduction in the numbers of patients requiring pethidine, and in the amount of pethidine given, in those who received an indomethacin suppository 1 h before operation compared with those who had a dummy suppository. Almost 100 patients took part, but the method of determining the analgesic efficacy may not have been sensitive enough. The recovery room nurses, who were unaware of the preoperative medication, gave either pethidine or a combination of paracetamol and codeine for postoperative pain at their discretion and at apparently different doses. Only pethidine consumption was recorded and pain was not scored. The method was unable to detect a difference in pain levels caused by clip or ring sterilization.

Edwards and colleagues[29] also demonstrated a lower pain score after laparoscopic sterilization at 20 min and 1 h and 20 min after diclofenac i.m. (compared with no injection) and, although the median of one pain score was more than 3 SEM less than the other, the difference between the two groups of 20 patients was not significant.

Significantly reduced opioid requirements after diclofenac 75 mg for diagnostic laparoscopy but not for laparoscopic sterilization have been reported,[39] although even in the latter procedure, the diclofenac group required slightly less fentanyl and paracetamol after operation. Perhaps a lack of difference or lack of sensitivity can be found in the method of pain titration and in the timing of assessment. Pain was not scored. Analgesics in large aliquots (fentanyl 50 μg i.v. or paracetamol 0.5 g rectally) were given "according to clinical judgement". Observer scores of pain were usually less than those of the patient and there would be reluctance to use additional large doses for small increases in pain. Diclofenac was given after induction of anaesthesia and approximately 27 min before the end of anaesthesia, possibly 30 min before the first assessment of pain and analgesic requirements. However, Green and colleagues were also able to detect a differential benefit for NSAID after diagnostic laparoscopy[37] but not after laparoscopic sterilization.[36]

Prados and Blaylock[76] found no benefit of ketorolac 30 or 60 mg given 15–20 min before the end of surgery, as tested by the use of patient administered and controlled fentanyl. Ketorolac was given i.m. and titration of analgesic to pain in the recovery room might be expected to be achieved without the influence of ketorolac but the amount of analgesic self-administered during admission was only marginally reduced in the ketorolac 60 mg group and not in the ketorolac 30 mg group.

Windsor and co-workers[96] found a non-significant improvement in pain score and a reduction in the number of rescue doses of fentanyl after tenoxicam i.v. at induction of anaesthesia. Pain and pain rescue were measured over 24 h. Tenoxicam is slow in analgesic onset and the peak action may be too late to treat pain susceptible to NSAID.

Although the provision of pain relief in the recovery period is variable and the efficacy of analgesics is dependent on patient expression of

Table 4 Assessment of pain and analgesic requirement in randomized controlled comparisons of NSAID and placebo

Reference	Significant effect of NSAID found	Assessment of pain	Assessment of additional analgesic requirement
Mclennan and colleagues[63]	No	Not stated	Amount and type given on discretion of staff
Edwards and colleagues[29]	No	Visual analogue scale (VAS)	Paracetamol, co-proxamol or pethidine given by nurse on request by patient
Edwards and colleagues[29]	No	Visual analogue scale (VAS)	Paracetamol, co-proxamol or pethidine given by nurse on request by patient
Crocker and Paech[19]	No	VASat 0 5, 1 and 3 h	Pethidine 25 mg doses i.v. titrated to patient comfort
Hovorka and colleagues[39]	No	Three-point rating scale assessment by observer	Paracetamol or fentanyl given on observer's judgement of pain
Shapiro and Duffy[83]	No	VAS at 1 and 5 h, peak VAS	Standard protocol: amount recorded
Windsor and colleagues[96]	No	Linear analogue scale and verbal rating scale	Patient request to nurses and pain diary
Davie and colleagues[22]	Yes	Linear analogue scale (LAS) + interview	Patient demand when tolerance exceeded
Brodie and Casper[8]	Yes	Nurse's judgement of analgesic need	Standard protocol of variable analgesia (not double-blind)
Huang and colleagues[40]	Yes	1–5 verbal rating scale	Morphine, meclofenate or paracetamol
Delucia and White[24]	Yes	0–100 las (averaged)	Fentanyl or ketorolac used as rescue analgesia
Delucia and White[24]	Yes	0–100 las (averaged)	Fentanyl or ketorolac used as rescue analgesia
Comfort and colleagues[17]	Yes	VAS at 1 and 2 h	Amount of paracetamol, codeine, pethidine or morphine determined by nurse
Gillberg and colleagues[33]	Yes	10 cm visual analogue scale (VAS)	Pethidine or paracetamol given by nurse
Hovorka and colleagues[39]	Yes	Three-point rating scale assessment by observer	Paracetamol or fentanyl given on observer's judgement of pain
Liu and colleagues[56]	Yes	VAS at 30, 60 90 min postop.	Standard protocol of different analgesics
Van Ee and colleagues[93]	Yes	0–10 numerical rating scale	Paracetamol/naproxen provided on patient request
Green and colleagues[37]	Yes	10 cm visual analogue scale (VAS)	Incremental i v. doses of fentanyl 25 μg
Wilson and colleagues[95]	Yes	10 cm visual analogue scale (VAS)	Morphine 10–15 mg prn
Dunn and colleagues[28]	Yes	Five-point verbal rating scale in recovery and at 2 and 4 h	Mefenamic acid and/or diamorphine on nurse's judgement

demand or nurses' perceptions of pain, even before pain severity is scored, the same objections apply also to those studies in which a significant analgesic effect for NSAID was found (table 4).

NSAID AND SHOULDER PAIN

If the pain perceived in the tips of the shoulders is related to inflammation of the peritoneal reflections supplied by the phrenic nerve, this may also be reduced by anti-inflammatory analgesics.

Although Crocker and Paech[19] found that global pain after laparoscopy and mean requirements for pethidine were less after indomethacin than after placebo ($P=0.09$ or 0.07), shoulder and chest pain was higher in the indomethacin group. Van Ee, Memrika and Van der Linden[93] gave naproxen 500 mg or dummy suppository 1 h before laparoscopy. The control group required more additional analgesics and had higher pain scores than the naproxen group, but the incidence of shoulder tip pain was not different in the two groups. Edwards and colleagues[29] studied women who had undergone either diagnostic laparoscopy or laparoscopic tubal ligation. In each group, patients were given diclofenac 75 mg after induction or no injection. Shoulder pain was noted separately but analgesia was given for total pain. The laparoscopic sterilization group had, on average, significantly more pain than the diagnostic laparoscopy group. Pain scores were lower in the diclofenac group on each assessment but the differences were not significant.

TIMING

The timing of NSAID administration and onset has been reviewed by Moote.[69] There is clearly a latency in onset of analgesic action and a longer delay before peak action. Rosenblum and co-workers[79] showed that the analgesic effect of ibuprofen was apparent only after the patient had left the recovery room. Davie, Slawson and Burt[22] gave oral fenoprofen 200 mg and saline injection when patients complained of pain in a double-blind, double dummy, placebo-controlled study. The assessment was an interview and a 10-cm linear analogue scale. Although those who received fenoprofen had less pain than those who received placebo after 1 h, the difference was not significant until 2 h. Van Ee, Memrika and Van der Linden[93] found naproxen to be more effective than placebo only 30 min after operation, or approximately 2 h after administration of the naproxen suppository.

In the studies which failed to demonstrate a significant analgesic effect of NSAID, the drug was usually given at or after induction of anaesthesia, that is approximately 30 min before rescue analgesia was available for pain in the recovery room, except where indomethacin was administered rectally 1 or 2 h before operation.[19 63] In those in which more than one assessment of pain or analgesic consumption was made, the greatest difference between NSAID and placebo effect was found at 2.5, 4 or 5 h after i.v. or i.m. administration. Similarly, in those studies in which NSAID demonstrated a significant analgesic effect, the greatest effect was found between 2 and 24 h after administration. Dunn, Clark and Jones,[28] using a relatively large dose of the long-acting agent naproxen did not find variation in analgesia with time over the first 24 h.

After oral absorption, there is a delay to peak plasma concentrations of most NSAID of approximately 1–2 h.[89] There may be further delay before peak concentrations at the site of action are reached. For example, regional concentrations of prostanoids within the fallopian tube suggest that surface generation may be less than in the lamina propria, for example. The data sheet for ketorolac (1996–1997) states that "the time to onset of analgesia effect after both intravenous and intramuscular administration is similar and is approximately 30 minutes with maximum analgesia occurring within one to two hours". (The evidence for this statement is difficult to trace in any single study, either by literature search or by direct enquiry to the information service at Syntex (Roche).) Similar data for the peak analgesic effect of i.v. diclofenac are not readily available but the same delay would be expected.[44] Pain assessment and analgesic administration may be occurring before NSAID become effective. It might be argued that NSAID were delayed in onset because they had no effect against prostanoids already synthesized.[69]

Another mechanism may be operative. It is possible that accumulation of the "right-handed" stereoisomer (R enantiomer) may be responsible for the build-up of analgesic effect. The S enantiomer of most (if not all) NSAID shows more anti-inflammatory activity than the R enantiomer, yet the analgesic activity of flurbiprofen for example, is related to both the R and S enantiomers, and prostaglandin inhibition within the brain is significantly inhibited by the pure R enantiomer.[9] Although many NSAID show one-way conversion of R to S enantiomer, via acetyl co-enzyme A for example, this is not universal or (with the exception of ibuprofen) extensive. One-way conversion does not occur with ketorolac in humans[67] but the R form has a half-life approximately twice that of the S form and would accumulate with repeated doses and dominate with time.

NSAID might provide pre-emptive analgesia. A noxious stimulus causes spinal and supraspinal processing, such as "wind-up" at the NMDA channel in the spinal dorsal horn, thereby increasing the throughput of the second-order spinal pain transmission neurones from a given input from the nociceptor through the first-order C fibre nociceptive afferent. If effective analgesia is present before the nocigenic stimulus, there is less wind-up and the total pain experience and total amount of analgesia required is less.[97] However, the pain of the early postoperative period, either by moderate or strong nocigenic stimuli or by mechanical, thermal or noxious stimuli in the presence of inflammation and hyperalgesia, can also cause wind-up.[49] Comparison of the effect of diclofenac given before laparoscopy with that of diclofenac given after did not show any difference in pain or analgesic requirements in the postoperative period.[10] Although allowance was made for the time required for diclofenac to exert its analgesic effect, it did not take into account the nocigenic stimuli in the early postoperative period.

ELIMINATION OF BIAS

In 1983, Dunn and colleagues[27] compared premedication with zomepirac 100 mg, an obsolete NSAID, with codeine 8 mg for prevention of pain after dental extraction and laparoscopy. The assessments of the procedures were considered separately. The study was prospective, randomized, double-blind and double-dummy, and assessments were a 10-cm vertical linear analogue scale and a five-point verbal rating scale. Systemic and local analgesics, with the exception of nitrous oxide, were not used in the general anaesthetic technique. Rescue analgesia was available. Analysis of those who required rescue medication was separated from those who did not. At 5 h after operation, all but one patient in the codeine group had received additional analgesia. Pain scores and rates of re-medication in each group were similar and only by 4 h was there a moderate, but not significant, difference in favour of zomepirac. (Pain scores and rates of re-medication in dental patients suggested that zomepirac was significantly more effective.) The study was not subjected to analysis to estimate the likelihood of demonstrating a difference between the two treatment groups but, in other respects, it achieved a higher standard of objectivity than most that followed. The subsequent study of Brodie and Casper,[8] which has been cited and discussed by almost half of the reports of the randomized studies that followed, was not double-blind (the treatment being dependent on the last digit of the hospital number), nor was pain assessment objective.

Only before the studies of Dunn, Clark and Jones[28] and MacLennan and co-workers[63] was the sample size calculated to achieve an 80% probability of detecting a material difference between the two groups of pain scores or between the numbers requiring analgesia. However, the numbers of patients in the studies which showed NSAID to be superior to placebo were not materially greater than those in studies which failed to show a significant effect.

There are many other studies and reviews or audits of the efficacy of analgesics for pain after laparoscopy, but only randomized controlled studies are included here.

ASSESSMENT OF OUTCOMES (SEE ALSO TABLE 4)

Almost all studies described have used patients' assessments of pain, either with a linear analogue scale, some other form of visual analogue scale, numerical rating scale or with a verbal rating scale. Verbal rating scales show a high level of correlation with linear analogue scores.[51] Occasionally, pain scores were treated not as ordinal data but subjected to parametric analysis and averages compared.[24] This may be defensible.[51] Prados and Blaylock[76] used fentanyl by patient-controlled administration to determine analgesic requirements after outpatient gynaecological surgery which required intubation and ventilation. Unfortunately, the report does not state that all were laparoscopies. However, in one study[8] the method of pain scoring was left to a nurse in recovery and the investigators were not blinded. In another,[63] a large, randomized, double-blind, double-dummy study, with pre-study power analysis, no assessment of pain was made by the patient and two types of rescue analgesia were administered according to patient demand and staff discretion. The study was unable to show any differences between the pain of tubal occlusion by clips and that with rings, as demonstrated by others[14 26]

REVIEW OF REVIEWS

There have been many reviews of NSAID in general, and individually, with regard to their pharmacology, uses and efficacy; few have considered their place in postoperative pain after laparoscopy[16 47 69] and even fewer have adequately considered analgesic requirements in reviews of laparoscopy.[81] The former have described the divergence of opinion of efficacy in comparison with either placebo or with other analgesics. They have commended for consideration the concept of balanced analgesia although there is little evidence for potentiation of quantity or quality of analgesia after laparoscopy and there is evidence of the disadvantage of a greater range of unwanted side effects. Only Schoeffler, Diemunsch and Fourgeaud[81] considered the different types of pain, different mechanisms and some of the various stratagems for overcoming them.

THE PLACE OF NSAID FOR POST-LAPAROSCOPY PAIN

That NSAID are most appropriate for pain after laparoscopy has not been proved. Even the additional pain caused by tubal ligation, possibly mediated by prostaglandins, does not appear to be ideally treated by prostaglandin synthase inhibitors. In one study, pain was relieved better after diagnostic laparoscopy and in another after tubal ligation. Does reduction in opioid use have a clinical advantage? Except in rare cases the need for opioids, especially when given judiciously and frequently, is unlikely to compromise ventilation. The reduced need for opioids is often postulated to reduce nausea and vomiting, ileus and time to readiness for discharge. Yet, usually no difference is found in the times of recovery to the various stages of autonomous function. Nausea and vomiting accompany the pain of both tubal occlusion and dysmenorrhoea[40] and may be unrelated to the use of opioids. Conversely, the antiemetic advantage of propofol for day-case anaesthesia is reduced or lost when papaveretum or morphine is used.[59 66 68] It would seem necessary to administer NSAID 1 h or more before laparoscopy to gain the maximum benefit after operation. At this stage, the accentuated risks of refractory bleeding, hypovolaemia or renal failure are not yet apparent. Bleeding is more difficult to detect and control during laparoscopy than laparotomy. Some studies and other reviews[16] have suggested that the quality of analgesia and patient satisfaction is improved if both NSAID and opioids are used. However, Davie and Gordon[21] have shown that fenoprofen and paracetamol used alone in modest doses were not significantly more effective than placebo, but in combination were significantly superior. This combination would appear to be more suitable for day surgery than the addition of opioids. Despite all the above, it is possible that the measures of pain, usually at rest rather than on movement, and well-being, are too insensitive and that the clinical impression of the nursing staff, based on the summation of many visual and verbal stimuli, should be quantified and tested. It is equally possible that the perception of pain relief by NSAID is an extrapolation from operative models in which NSAID have a more noticeable effect.

Conclusion

Pain which is caused by laparoscopy and laparoscopic surgery is variable in duration, severity and character. The tendency towards reduced hospital stay for laparoscopic procedures leads to failure of recognition and treatment of pain which arises or increases after the first few postoperative hours. Pain which is severe after hospital discharge makes necessary high-cost domiciliary visits and possibly inadequate treatment because of the constraints of the lack of monitoring.

Local anaesthetic techniques, regional or focal, appear more successful for pelvic laparoscopy than for laparoscopic cholecystectomy for example, although interpleural anaesthesia may be effective and safe for unilateral pain. Pain related to stimulation of the phrenic nerve is not easily resolved by extradural anaesthesia without considerable risk or life support.

Non-steroidal anti-inflammatory drugs and paracetamol are not as effective for immediate postoperative pain as are opioids and appear to be ineffective for pain in the shoulders. Their effect in the majority of patients is to reduce the severity of pain or to reduce the need for opioid analgesia. As a sole analgesic, they appear inadequate in most patients. The evidence that the use of NSAID increases recovery or hospital discharge is not consistent. Single intraoperative doses of short-acting opioids such as fentanyl are also inadequate for pain in most cases. However, in many patients, NSAID, given sufficiently early to be effective by the time of waning of the effect of the peroperative opioid, are sufficient to render discomfort tolerable.

Until the various pains are assessed separately and analgesic stratagems are assessed for the different components of the pain experienced, most of these pain-relieving methods will be ineffective because the remaining pain is a sufficient cause of dissatisfaction to maintain demands for rescue analgesia and to increase pain scores. A combination of simple measures, such as evacuating the insufflated gas, application of local anaesthetic gel to the fallopian tubes at the time of clipping, use of a rectus sheath block or local anaesthetic applied to skin and muscle wounds, preoperative use of paracetamol and use of a moderately short-acting intraoperative opioid may reduce the immediate and referred pain effectively and safely. The later inflammatory pain can then be modified with non-opioid drugs such as the anti-inflammatory agents.

Twitch augmentation and train-of-four fade during onset of neuromuscular block after subclinical doses of suxamethonium

S. Y. KIM, J. S. LEE, S. C. KIM AND W. PARK

Summary

We have studied the train-of-four (TOF) response mechanomyographically during onset of neuromuscular block produced by subclinical doses of suxamethonium in order to follow the augmentation of the first twitch of the TOF (T1) and TOF fade compared with control TOF responses before the drug was given. In the groups given suxamethonium 0.05, 0.1, 0.2 and 0.3 mg kg^{-1}, the increments in T1 after administration of the drug were observed before twitch depression occurred; these were mean 22.3 (SEM 8.1) %, 19.2 (3.3) %, 10.8 (2.0) % and 4.2 (2.2) %, respectively. This effect was more marked with the lower doses ($P<0.05$). The degree of TOF fade was moderate during onset of neuromuscular block and depended on the dose of drug. The results of this study suggest that low doses of suxamethonium produced transient increase in muscle tension and twitch depression with significant TOF fade. We conclude that suxamethonium was associated with presynaptic effects as a consequence of brief stimulation of acetylcholine release followed by progressive diminution at the neuromuscular junction. (*Br. J. Anaesth.* 1997; **79**: 379–381).

Key words
Neuromuscular block, suxamethonium. Neuromuscular block, measurement of response.

It is generally accepted that suxamethonium acts on postjunctional structures causing depolarizing block. This block is the result of opening of cation channels by activation of acetylcholine receptors on the α subunits of the postsynaptic receptor pentamer. However, some investigators have produced evidence that the drug may act on both pre- and postsynaptic receptor sites at the neuromuscular junction.[1] The presynaptic effect of a large amount of acetylcholine is to produce a transient increase in muscle tension because of postsynaptic stimulation followed by depression of neuromuscular transmission as a consequence of inhibition at presynaptic receptors at motor nerve endings.[2] The fade of train-of-four (TOF) response is accepted as a consequence of the presynaptic effect resulting from progressive diminution of the output of acetylcholine.[3] Therefore, we have investigated the simultaneous appearances of these two responses induced by subclinical doses of suxamethonium.

Methods and results

Approval for this study was obtained from the Ethics Committee of Soon Chun Hyang University Hospital. We studied 48 healthy adult patients, ASA I or II, undergoing elective surgery and not suffering from any neuromuscular, renal or hepatic diseases, or receiving any medication which might influence neuromuscular transmission. Patients with a personal or family history of suxamethonium apnoea or malignant hyperthermia were excluded.

Patients were given glycopyrronium 0.2 mg and nalbuphine 10 mg i.m., 1 h before induction of anaesthesia. An i.v. infusion was commenced when the patient arrived in the operating room, and ECG, end-tidal carbon dioxide, oesophageal temperature and arterial pressure were monitored. Surface electrodes (Red Dot, 3M Ag/AgCl) were applied over the ulnar nerve at the wrist and supramaximal TOF stimulation at a frequency of 2 Hz for 2 s delivered by a peripheral nerve stimulator (Innervator, Fisher and Paykel, New Zealand) using 0.2-ms square wave pulses. The trains of stimuli were repeated every 12 s. The twitch response of the thumb adductor was measured mechanomyographically using a cell strain gauge with a 2-kg load (Model No. 505H, RS Component Ltd, UK) with thumb piece modification. Recordings were made on a Gould TA 240 Easy Graf thermal array recorder with a 6600 series transducer.

After thiopentone 4–5 mg kg^{-1} for induction, anaesthesia was maintained with 66% nitrous oxide in oxygen with increments of thiopentone or fentanyl 1 $\mu g\ kg^{-1}$, or both, as required. Ventilation of the lungs was assisted using a face mask, when necessary, to maintain normocapnia. The patient's core temperature was maintained within the normal range. In this study, subclinical doses of suxamethonium were used in order to measure the effect on twitch height and TOF, because it is difficult to obtain TOF responses during the short onset time of

neuromuscular block induced by clinical doses of suxamethonium. After induction of anaesthesia, twitch height of the TOF was allowed to stabilize for at least 10 min and patients were allocated according to randomly selected numbers to receive one of the following subclinical doses of suxamethonium: 0.025, 0.05, 0.1, 0.2, 0.3 or 0.4 mg kg^{-1} i.v. via an indwelling needle at the wrist. Eight patients received each dose.

Neuromuscular recording was continued to measure the following: (1) twitch augmentation (%), defined as the maximum increase in T1 compared with control T1; (2) maximum T1 depression (%), defined as the greatest depression of T1 after injection; and (3) change in TOF ratio (%). This was calculated from the first TOF ratio at the depressed height of T1 during onset after injection and at the corresponding height level of T1 during recovery.

Statistical analysis was performed using SPSS. Results were compared using Kruskal–Wallis one-way analysis of variance (ANOVA) and groups which differed significantly by ANOVA were tested with Student–Newman–Keuls multiple range test to determine differences between groups. The TOF ratio during onset was compared with that during recovery in each group using the paired Student's *t* test. Differences were considered statistically significant at $P<0.05$. Data are reported as mean (SEM).

Twitch augmentations of TOF responses after drug administration were observed before depression of T1 and were greatest for T1 for the four twitch responses of TOF: 22.3 (8.1) %, 19.2 (3.3) %, 10.8 (2.0) % and 4.2 (2.2) % in the groups given suxamethonium 0.05, 0.1, 0.2 and 0.3 mg kg^{-1}, respectively. This effect was more marked with the lower dose ($P<0.05$) (table 1) and was not observed in groups given 0.025 and 0.4 mg kg^{-1}. Partial depression occurred in groups given suxamethonium 0.05, 0.1 and 0.2 mg kg^{-1} and almost complete T1 depression occurred in groups given 0.3 and 0.4 mg kg^{-1}. However, there were no changes in TOF response in the suxamethonium 0.025 mg kg^{-1} group. The degree of TOF fade at the first TOF during onset after drug administration was moderate: 76.5 (1.0) %, 70.3 (1.4) %, 68.7 (1.8) % and 68.6 (1.7) % in the groups given suxamethonium 0.1, 0.2, 0.3 and 0.4 mg kg^{-1}, respectively. TOF fade depended on the dose of drug given. Almost sustained TOF responses occurred during recovery and TOF fade during onset of neuromuscular block was significantly greater than that at the corresponding height of T1 during recovery from neuromuscular block ($P<0.05$) (table 1).

Comment

It is thought that there are at least two populations of presynaptic cholinergic receptors, each subserving different physiological functions: one group is the presynaptic nicotinic receptor which acts as a positive feedback and responds to low concentrations of acetylcholine causing an autofacilitatory effect. This is believed to be mediated partly through its action on synapsin I causing an increase in the immediately available store of acetylcholine increasing the rate of release of acetylcholine after motor nerve activity. The second group is the presynaptic muscarinic receptor which acts as a negative feedback and responds to high concentrations of acetylcholine. Stimulation of these receptors causes reduced release of transmitter in the presence of motor nerve activity. This would explain the response observed experimentally after a large dose of acetylcholine is injected directly into the arterial supply of a muscle; initial powerful contraction is followed by transient neuromuscular block.[2] There is convincing evidence of a physiological mechanism of this type causing an initial positive feedback via autoreceptors on the nerve endings and then negative feedback limiting the effect of the high concentration released.[4] As suxamethonium produces an acetylcholine-like action, it has been proposed that neuromuscular block by this drug is the result of both pre- and postsynaptic sites of action.[5] We have demonstrated that twitch augmentation produced by suxamethonium was apparent in the groups given doses which only partially depress T1 and it was absent in the groups given doses which were either too small to cause block or too large. The results could be explained by proposing that suxamethonium causes brief stimulation of intact presynaptic receptors on motor nerve endings increasing the mobilization of acetylcholine. Any effect is overwhelmed by a large dose which causes complete block. Therefore, it seems likely that suxamethonium, which in some respects resembles acetylcholine, may initially evoke activation of presynaptic cholinergic receptors which augments depolarization of the postsynaptic membrane. Its action then progresses to cause presynaptic depression, block or desensitization.[5]

TOF fade is generally attributed to a presynaptic effect caused by progressive decrease in acetylcholine release from the nerve endings.[6] Presynaptic binding of neuromuscular blocking agents prevents rapid acetylcholine mobilization required to maintain adequate acetylcholine release during rapid stimulation, such as during TOF or tetany. The generally accepted view is that the degree of fade is related to the propensity for presynaptic binding and demonstration of fade can be taken as evidence of presynaptic block of a feedback mechanism.[5] Full depolarizing block induced by suxamethonium is characterized by lack of fade but repeated doses or continuous infusion of drug produces neuromuscular block characterized by tetanic fade, termed phase II block. However, in our study, despite administration of subclinical, small doses of suxamethonium, the TOF response appeared to be associated with approximately 70% TOF fade during onset of block; even during recovery from block, TOF fade did not occur. Otherwise, it is presumed that the moderate fade of TOF response during onset after subclinical doses of suxamethonium results from incomplete block of presynaptic receptors and the sustained TOF response during recovery should result from rapid dissociation from presynaptic sites by enzymatic hydrolysis at the early stage of recovery. However, the different effects observed on TOF fade and T1 depression may be caused by different affinities and rates of binding for pre- and postsynaptic receptors at the neuromuscular junction.[3]

The results of this study suggest that the hypothesis that, although the site of action of suxamethonium is postsynaptic it also has a presynaptic site of action, may be true, but clinically it is masked by large doses.

Spontaneous movements associated with rocuronium: is pain on injection the cause?

A. BORGEAT AND D. KWIATKOWSKI

Summary

Spontaneous movements are sometimes observed of the arm into which rocuronium is administered. In order to assess a possible relationship between these movements and pain, we injected in 10 awake, ASA I patients, in a double-blind manner, both rocuronium 1 ml (10 mg) and 0.9% NaCl 1 ml (placebo), with a 30-s interval in between. None of the patients receiving placebo complained of pain, but eight of 10 patients reported a strong burning pain during injection of rocuronium with brisk flexion of the elbow and wrist, similar to those observed in patients after induction of anaesthesia. A second injection of rocuronium did not produce such pain and no movements were observed. We conclude that injection of rocuronium is associated with severe, burning pain of short duration, responsible for the spontaneous movements in the arm observed after induction of anaesthesia. (*Br. J. Anaesth.* 1997; **79**: 382–383).

Key words
Neuromuscular block, rocuronium. Pain, injection.

Rocuronium bromide is a new steroidal non-depolarizing neuromuscular blocking drug, related structurally to vecuronium and characterized by a rapid onset and intermediate duration of action.[1 2]

In the recent past, we observed in some patients the occurrence of sudden flexion, lasting 10–20 s, of the wrist and arm into which rocuronium was infused. Although this compound is considered to be tolerated well during injection, recent reports indicate severe burning pain after i.v. injection of rocuronium.[3–5]

The aim of this study was to assess and characterize the nature of the pain and to investigate the possible association between pain and spontaneous movements during administration of rocuronium.

Methods and results

After obtaining institutional Ethics Committee approval and informed patient consent, we studied 10 patients, ASA I, aged 20–40 yr, weighing more than 70 kg and undergoing elective orthopaedic surgery.

All patients were premedicated with midazolam 0.1 mg kg^{-1} orally, 1 h before induction of anaesthesia. An 18-gauge i.v. cannula was inserted into the dorsum of the hand and a tourniquet inflated slowly on the same side until the patient considered it uncomfortable; then it was deflated by 10 mm Hg in order to create venous stasis without any pain. In the first part of the study each patient received randomly, in a double-blind manner, both rocuronium 1 ml (10 mg) and 0.9% NaCl 1 ml (placebo) with an interval of 30-s in between. The vials were stored at room temperature at least 2 h before administration and were prepared and coded by an independent investigator. Thirty seconds after administration of the second drug, the tourniquet was deflated slowly and the patient received a bolus dose of propofol 3 mg kg^{-1} in order to assure rapid induction.

In the second part of the study another five patients received two successive injections of rocuronium 1 ml (10 mg) at 30-s interval, following the same procedure as described previously.

In the third part of the study 10 more patients received two successive injections of either 0.9% NaCl 1 ml (pH 5.3) or 0.9% NaCl 1 ml adjusted to a pH of 4, according to the same procedure as described previously. NaCl 0.9% was buffered at pH 4 by adding 20% hydrochloric acid 0.02 ml to 0.9% NaCl 1000 ml (ABL 505 Radiometer Copenhagen). The vials were prepared and coded by our pharmacist.

Pain was scored on a VAS from 0=no pain to 10=strongest pain imaginable. The patient, when pain was present, was asked to orally score its intensity and describe its nature. Any movement associated with pain was observed carefully by one of the investigators.

In the first part of the study no patient felt any pain (VAS=0) when receiving placebo. Eight of 10 patients complained of severe pain during injection of rocuronium (VAS=10) which lasted for approximately 10–20 s; one patient reported moderate pain (VAS=5) and the last patient an unpleasant feeling (VAS=2). The pain was described by all patients as

intense and burning. The first eight patients had sudden flexion of the elbow and wrist at the same time; the two others showed only slight flexion of the wrist.

In the second part of the study all five patients complained of severe burning pain after the first injection with flexion of the elbow and wrist, as described previously (VAS=10). In contrast, after the second injection three patients had moderate pain (VAS=4) and the other two only an unpleasant feeling (VAS=2). All five patients reported that pain was greatly decreased during the second injection. No erythema or any change in the skin surrounding the point of injection or the arm was observed. Twenty-four hours later there was no vein induration and no patient complained of residual pain. At the end of the surgical procedure, patients recalled the pain, but none had any memory of respiratory difficulties.

In the third part of the study no patient complained of pain (VAS=0) when receiving either 0.9% NaCl pH 5.3 or 0.9% NaCl adjusted at pH 4.

Comment

We have demonstrated that administration of rocuronium was associated with severe burning pain on injection which lasted for approximately 10–20 s. In most cases brisk flexion of the elbow and wrist was observed simultaneously during i.v. injection of rocuronium. Interestingly, after a short interval of time, the pain was greatly decreased during a subsequent second administration of the drug.

Our results confirm earlier reports[3–5] describing the burning pain associated with administration of rocuronium before induction of anaesthesia. Of interest is the observation that the brisk flexion of the elbow and wrist noted in patients after induction of anaesthesia was similar in nature and duration to that observed in awake patients.

The mechanism by which rocuronium causes pain is unclear. Rocuronium is supplied in a sterile, nonpyrogenic, isotonic solution. Isotonicity is obtained with sodium chloride and a pH of 4 by adding acetic acid or sodium hydroxide. The osmolality (osmol litre^{-1}) and osmolarity (osmol kg^{-1}) are between 260 and 330.[6] The relatively low pH of the rocuronium solution may be a possible cause, as Klement and Arndt[7] have shown that injection of acidic solutions with a pH of 4 or less causes pain on injection, which increased linearly with a lower pH. However, the authors noted that after injection of acidic solutions, perivenous oedema developed immediately and was followed by thrombophlebitis for up to 3 weeks, which was not the case in this study.[7] Moreover, the absence of pain in patients receiving 0.9% NaCl 1 ml adjusted to pH 4 argues against such a possibility. Interestingly, vecuronium is buffered at a pH of 4 and has not been associated with pain on injection.

The short duration of the pain and marked decrease or absence of pain during a subsequent second administration led us to speculate that local release of mediators may be implicated in this reaction. Histamine is unlikely as neither erythema nor warmth in the surrounding tissue was observed or reported. Other mediators such as a kininogen cascade may be involved; this was postulated to explain the pain associated with propofol injection.[8] The pain associated with propofol and rocuronium is similar: it appears immediately during administration, duration is short and intensity decreases with subsequent injection.

Rocuronium should not be given to awake patients (e.g. priming). We believe that the similarities of movements of the arm observed in the awake patient and after induction of anaesthesia indicate that the movements observed in anaesthetized patients are the direct consequence of pain associated with administration of rocuronium. In order to avoid this side effect, it is important to inject rocuronium only when a deep stage of unconsciousness has been reached.

Rapid tracheal intubation with propofol, alfentanil and a standard dose of vecuronium

R. GROENER AND D. G. MOYES

Summary

We studied 60 ASA I patients with Mallampati grade 1 airways to compare emergency intubating conditions with either alfentanil 20 μg kg^{-1}, propofol 2.5 mg kg^{-1} and vecuronium 0.1 mg kg^{-1}, or with thiopentone 5 mg kg^{-1} and suxamethonium 1 mg kg^{-1}. Ease of laryngoscopy, vocal cord status and cough response were graded. The trachea of all patients was intubated; 83% of patients in the alfentanil–propofol–vecuronium group and 86% in the thiopentone–suxamethonium group were considered to have satisfactory intubating conditions at 60 s. We conclude that the combination of alfentanil 20 μg kg^{-1}, propofol 2.5 mg kg^{-1} and vecuronium 0.1 mg kg^{-1} provided adequate conditions for rapid tracheal intubation. (*Br. J. Anaesth.* 1997; **79**: 384–385).

Key words
Anaesthetics i.v., propofol. Analgesics opioid, alfentanil. Neuromuscular block, vecuronium. Intubation tracheal, technique.

Techniques using non-depolarizing neuromuscular blocking agents in place of suxamethonium for rapid tracheal intubation have entailed the use of higher doses or priming techniques. Propofol and alfentanil given in combination facilitate intubation[1]; the addition of vecuronium 0.1 mg kg^{-1} has not been evaluated in the attempt to achieve intubation within 60 s. The aim of this study was to investigate if the combination of alfentanil, propofol and vecuronium would provide intubating conditions for rapid tracheal intubation comparable with those produced with thiopentone and suxamethonium.

Methods and results

After obtaining Ethics Committee approval, we studied 60 ASA I patients, aged 22–58 yr, with Mallampati class 1 airway anatomy,[2] fasted before operation and undergoing elective surgery. Patients were allocated randomly to one of two groups. All patients received glycopyrronium 5 μg kg^{-1} and their lungs were preoxygenated for 3 min. Patients in group A (n=30) received a bolus dose of alfentanil 20 μg kg^{-1}, followed 60 s later by propofol 2.5 mg kg^{-1} over 15 s and vecuronium 0.1 mg kg^{-1}. Patients in group B (n=30) received thiopentone 5 mg kg^{-1} over 15 s followed by suxamethonium 1 mg kg^{-1}.

Cricoid pressure was applied by an assistant. Laryngoscopy and intubation were performed using a Macintosh 3 blade, 60 s after administration of the neuromuscular blocking agent, by one of two experienced anaesthetists who entered the room 40 s after the blocker had been given and were blinded as to group allocation. After assessing intubating conditions this anaesthetist left the operating theatre and took no further part in the procedure.

Intubating conditions were assessed by the scoring system of Helbo-Hansen, Ravlo and Trap-Andersen.[3] Intubating conditions were judged acceptable when each individual category score was 2 or less. Ease of laryngoscopy, vocal cord status and degree of coughing are shown in table 1.

Table 1 Intubating conditions. One patient in group B was not scored for vocal cords or coughing (see text)

	Group A	Group B
Laryngoscopy		
Easy	23	23
Fair	6	4
Difficult	1	3
Impossible	0	0
Vocal cords		
Open	29	27
Moving	0	2
Closing	1	0
Closed	0	0
Cough response		
None	24	27
Slight	3	1
Moderate	3	1
Severe	0	0

Monitoring included electrocardiogram (ECG), pulse oximetry (Sp_{O_2}) and a calibrated non-invasive arterial pressure (NIAP) device (Dinamap, Critikon). Anaesthesia was continued using 1% halothane and 50% nitrous oxide in oxygen. Heart rate (HR), Sp_{O_2} and mean arterial pressure (MAP)

were obtained at 1-min intervals until 5 min after intubation.

Parametric data were analysed using the unpaired Student's *t* test and one-way ANOVA via the Instat program (Graphpad Software Inc, San Diego, CA, USA). Intubating condition scores were analysed using the chi-square test with Yates' correction, or with the Fisher exact probability test if the minimum chi-square conditions were not met.

The groups were comparable in age, sex and weight. Intubation was achieved in all patients. There were no significant differences in intubating condition scores between the two groups. Twenty-five of 30 patients (83%) in group A and 25 of 29 patients (86%) in group B had satisfactory intubating conditions. One patient in group B, despite a Mallampati 1 grading, had a Cormack and Lehane grade 3 view[4] at laryngoscopy and his trachea was not intubated at 60 s. This patient was the only one whose trachea was intubated with a bougie, at the first attempt, and was not scored for vocal cord status or cough response.

There was no decrease in oxygen saturation to less than 98% in either group. There was a significantly increased heart rate and MAP ($P<0.0005$) at each time in group B compared with group A.

Comment

When used as the sole agent for intubation, propofol is associated with an increased incidence of bucking and coughing. The addition of alfentanil 20 $\mu g\ kg^{-1}$ reduces but does not eliminate this problem.[1] Keaveny and Knell[5] reported a 95% success rate of intubation using propofol 2.5 mg kg^{-1} alone in 20 patients. However, Coghlan, McDonald and Csepregi[1] achieved successful intubation in only 73% of patients given propofol 2.5 mg kg^{-1} alone and in 83% using alfentanil 20 $\mu g\ kg^{-1}$ in addition to propofol. These success rates are unacceptable for rapid sequence intubation.

The onset time of vecuronium is dose-dependent. In this study a dose of $2 \times ED_{50}$ was used, which has an onset time of 2–3 min.[6] However, the combined use of propofol and alfentanil provided adequate conditions for rapid tracheal intubation within 60 s.

Higher doses of non-depolarizing neuromuscular blocking agents, or the use of priming techniques, are advocated when rapid sequence induction is indicated and the use of suxamethonium is undesirable. The disadvantages of prolonged neuromuscular block with higher doses of non-depolarizing agents, and the discomfort and risks associated with priming techniques, are avoided with the alfentanil–propofol–vecuronium technique. In the event of a failed intubation, however, the use of a non-depolarizing neuromuscular blocking agent in place of suxamethonium removes the option of early resumption of spontaneous ventilation.

We conclude that the combination of alfentanil 20 $\mu g\ kg^{-1}$, propofol 2.5 mg kg^{-1} and vecuronium 0.1 mg kg^{-1} provided adequate intubating conditions for rapid tracheal intubation and may be used when the use of suxamethonium is undesirable.
